Equation 9 indicates that the magnitude of g_{cb} has a "break frequency" at $\eta\omega_{cb}$ and then decreases at the rate of −6db/oct. Measured characteristics of g_{cb} agree well with equation 9. Fig. 10 illustrates the graphical construction of the g_{cb} characteristic from the α_{cb} and Z_{io} characteristics. This is obtained by subtracting decibel magnitudes and phase angles as required by equation 5. At the g_{cb} break frequency the phase angle is of the order of −150 deg (degrees) rather than the characteristic −45 deg of a pure lag network. This means that when transistor feedback amplifiers are designed, particular attention should be given to the phase angle of g_{cb} which is quite different from what is normally encountered in vacuum-tube amplifier design in the same frequency range. Self-feedback has little beneficial effect on the rapidly changing phase angle at high frequencies. Consequently, the maximum stable loop gain which can be realized will be ultimately limited by the phase characteristic of g_{cb}, and not by the phase shift from stray circuit capacitance, etc., (as in the case of a vacuum-tube amplifier).

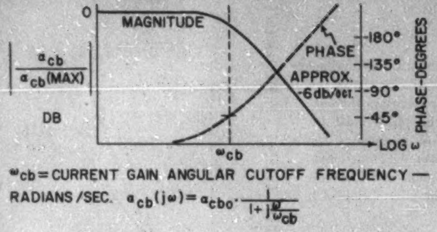
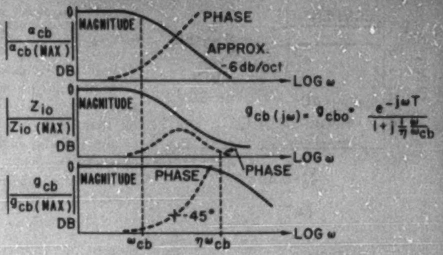
Computing Amplifier Design

The amplifier described in the following was not developed for any particular application, but is intended to show that contemporary commercial transistors are usable in high-gain feedback amplifiers. The design specifications given are typical of those imposed on a summing amplifier for use in a fire-control computer. In



ω_{cb} = CURRENT GAIN ANGULAR CUTOFF FREQUENCY — RADIANS/SEC. $\alpha_{cb}(j\omega) = \alpha_{cbo} \cdot \frac{1}{1+j\frac{\omega}{\omega_{cb}}}$

Fig. 8. Magnitude and phase characteristics of the short-circuit current gain α_{cb}, ω_{cb} = current-gain angular-cutoff frequency, radians per sec



$$g_{cb}(j\omega) = g_{cbo} \cdot \frac{e^{-j\omega T}}{1+j\frac{1}{\eta}\frac{\omega}{\omega_{cb}}}$$

Fig. 10. Illustrating the graphical construction of the $g_{cb}(\omega)$ characteristic from the $\alpha_{cb}(\omega)$ and $Z_{io}(\omega)$ characteristics

addition, the amplifier should be subminiaturized, thus precluding the use of high-Q inductance capacitance stabilization networks. For the present design a further, though perhaps unnecessary, restriction will not permit the use of transformers.

SPECIFICATIONS

Carrier frequency, 400 cycles per second ± 5%

Bandwidth, 100 cycles

Inputs, 2, independent

Input impedance, 100 kilohms resistive

Closed-loop gain, 1.0

Maximum dynamic error, ±0.1%

Minimum load impedance, 50 kilohms resistive

Operable temperature range, 20–65 degrees centigrade

PRELIMINARY DESIGN CONSIDERATIONS

For a closed-loop input resistance of 100 kilohms and for unity gain for each input, from equation 1 it is clear that $R_{i1} = R_{i2} = R_f =$ 100 kilohms. In the presence of self-feedback, it will be assumed that the total amplifier gain may decrease by 50% i.e., $(A\beta)n = 0.5$ which is approximately a 13% gain decrease per stage for a 5-stage amplifier. From equation 2 the required $(A\beta)o$ is 1,000 for an error of 0.1%. Since the design procedure is not unique, β may be arbitrarily chosen. However, the value chosen should not impose a severe amplifier-gain requirement. For this amplifier, β was chosen as 0.125, and consequently, as shown in Fig. 11, values of β, R_i, and R_f determine R_b'. To reduce the sensitivity of β to changes of the amplifier input resistance, and to reduce β frequency dependence, R_b should be small compared to R_{in}. In Fig. 11, where R_{in} = amplifier input resistance and R_b = base-shunting resistance, let

$$R_b' = \frac{R_b R_{in}}{R_b + R_{in}}$$

$$\beta = \frac{R_i'}{R_i' + R_f}$$

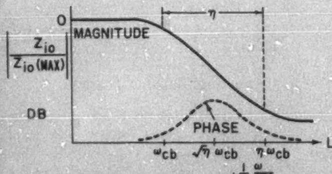
where $R_i' = R_{i1}$ in parallel with R_{i2} in parallel with R_b'. For $R_{i1} = R_{i2} = R_f = 100$ kilohms and $\beta = 0.125$, then $R_b' = 20$ kilohms. If $R_b = 1/3\ R_{in}$ then $R_b' = 3R_b/4 = 20$ kilohms, therefore $R_b \approx 27$ kilohms and $R_{in} \approx 81$ kilohms. Thus, the self-feedback resistances of the input stage are chosen to satisfy the input resistance requirement imposed by choice of a β value.

If the feedback resistance is very much larger than the open-loop output resistance and load resistance in parallel, and if direct transmission is neglected, then A is essentially equal to the amplifier voltage gain. For $A\beta = 1{,}000$ and $\beta = 0.125$, the required amplifier gain at the carrier frequency is 8,000. However, if it is assumed that the interstage compensation networks introduce about 2-db loss at the carrier frequency, then the amplifier gain must be increased to approximately 10,450 in order to account for this loss.

As a result of the input resistance requirement, the input stage will have a gain of approximately unity, and since an odd number of stages is required, the last two stages of a 3-stage amplifier must supply the total gain of 10,450, or a gain of approximately 102 per stage. This is not easily realizable with cascaded common-emitter stages without transformers. If a 5-stage amplifier is postulated, then the gain per stage (exclusive of the input stage) must be approximately 10. This is easily realized from cascaded common-emitter stages, and will still allow sufficient self-feedback for gain stabilization.

AMPLIFIER STABILIZATION

The first step in the stabilization process is determining the available fre-



$$Z_{io}(j\omega) = R_{io} \cdot \frac{1+j\frac{1}{\eta}\frac{\omega}{\omega_{cb}}}{1+j\frac{\omega}{\omega_{cb}}}$$

quency range in which the attenuation and phase may be controlled by interstage compensation networks. Except for impedance levels, the low-frequency stabilization problem is basically the same as in vacuum-tube amplifiers, and so will not be discussed.[10] However, as was shown, the phase shift of the transconductance will be the limiting factor at high frequencies, since it limits the frequency band in which effective compensation may be had to reduce the loop-gain below unity before the phase shift reaches −180 deg. A good engineering approximation is obtained if it is assumed that all transistors have the same g_{eb} gain and phase characteristics.

In the interests of simplicity and subminiaturization, the simple high-pass and low-pass networks of Fig. 12 are used for low- and high-frequency stabilization. Specification of the maximum network phase shift determines the ultimate attenuation ratio η, and therefore the ratio of network resistance to circuit resistance. The value of the capacitance fixes the network characteristics in a particular range of the frequency spectrum. Therefore, with the limiting attenuation and phase characteristics of the amplifier known, a stable loop-gain characteristic may be constructed. The results will dictate how many networks should be used, what their attenuation ratios should be, and at which frequencies they should be effective. The only additional information required to complete the design is the impedance level of the circuit in which the networks are to be placed. This procedure was followed in the present design and resulted in an unconditionally stable amplifier for the specified loop-gain of 1,000. Relatively few changes of component values were necessary to approximate closely the calculated $A\beta(\omega)$ characteristic. The high degree of prediction is attributed to the ability to determine the circuit impedance levels and gain in the presence of self-feedback.

The schematic diagram of an experimental 5-stage amplifier, based on the principles discussed thus far, is shown in Fig. 13.

Table I. Summary of Design Equations

Feedback	Input Impedance	Output Impedance	Current Gain	Voltage Gain
Voltage	$Z_{ivfb} \approx Z_{io} \parallel \dfrac{Z_f}{1+K_{vnfb}}$ $Z_f \gg Z_1$ $\alpha_{11} \gg 1$	$Z_{ovfb} \approx Z_{o\infty} \parallel \dfrac{Z_f}{1+\dfrac{\alpha_{11}Z_2}{Z_{in}}}$ $Z_f \gg Z_L$	$K_{ivfb} \approx \dfrac{K_{infb}}{1+\dfrac{Z_1}{Z_f}(\alpha_{11}+1)}$	$K_{vvfb} \approx \dfrac{K_{vnfb}}{1+Z^0\left[\dfrac{Z_1}{Z_2Z_f}+\dfrac{1}{Z_{ivfb}}\right]}$
Current	$Z_{icfb} \approx Z_{in}+(1+K_{infb})Z_e$ $Z_{o\infty} \gg Z_e$	$Z_{ocfb} \approx Z_{o\infty}\left[1+\dfrac{\alpha_{11}Z_e}{Z_e+Z_g+Z_{io}}\right]$ $Z_{o\infty} \gg Z_e$	$K_{icfb} \approx K_{infb}$ $Z_{o\infty} \gg Z_e$	$K_{vcfb} \approx \dfrac{K_{vnfb}}{1+\dfrac{Z_e}{Z_L}K_{vnfb}}$ $Z_{o\infty} \gg Z_e \quad K_{vnfb}Z_{io} \gg Z_L$
Total	$Z_{itfb} \approx Z_{ivfb}+(1+K_{ivfb})Z_e$	$Z_{otfb} \approx Z_{ovfb}\left[1+\dfrac{\alpha_{11}Z_e}{Z_g+Z_{ivfb}}\right]$	$K_{itfb} \approx K_{ivfb}$	$K_{vtfb} \approx \dfrac{K_{vvfb}}{1+\dfrac{Z_e}{Z_L}K_{vvfb}}$

Reasons for Design Choice

The construction of the open-loop attenuation and phase characteristic is arbitrary; consequently numerous stable characteristics could be realized. However, it might be well to point out some of the reasons for the choice that was made. In an a-c computer utilizing many amplifiers in cascade it is important to keep the closed-loop phase shift small in the useful frequency band. This may be achieved by making the open-loop phase shift small in this range. Since the low- and high-pass stabilization networks introduce lagging and leading phase shifts respectively, their effects tend to cancel in the region about the carrier frequency. Ideally, if the network break frequencies had a geometric mean frequency exactly equal to the carrier frequency, exact cancellation would result. In the present design, this procedure was followed as far as possible. At frequencies considerably higher than the carrier frequency, transistor phase shift dominates, and thus carrier-frequency symmetry is lost. For the transistors used, the high-frequency phase shift was so severe that additional low-pass networks were no longer effective for gain-phase compensation. This problem is solved if a leading phase can be introduced at high frequencies which will partially offset the rapidly changing transistor phase shift. A cascade lead network is undesirable because of the accompanying low-frequency attenuation. Another means is making the β network exhibit phase lead properties by placing a capacitance in shunt with the feedback resistance. The minimum frequency at which the maximum phase lead may occur is dictated by how much residual phase shift is allowed at the carrier frequency, since this amount of phase shift will appear in the closed loop.

Test Results

Measurements on the circuit of Fig. 13 show that a stable loop gain of 60 db is obtained and that the static amplitude and phase errors may be reduced to a negligible amount when the loop gain is set at its design center value. Interchanging of transistors between stages and the insertion of randomly chosen, available transistors did not cause a dynamic error in excess of 0.1% at a signal input of 3.0 volts rms.

Fig. 14 is a plot of the closed-loop magnitude response of the circuit of Fig. 13. The magnitude of the resonant peaks gives an indication of the degree of stability. Fig. 15 shows the open-loop gain temperature characteristics. The rapid decrease above 65 degrees centigrade is attributed to the inability of self-feedback, using only pure resistance elements, to control I_{co} at these elevated temperatures. It is felt that this temperature characteristic could be improved considerably by using temperature-sensitive self-feedback elements such as thermistors and thyrite resistors.

Although exhaustive tests of the amplifier of Fig. 13 were not made, the limited results are encouraging, for this study indicates that high-accuracy analogue-computing amplifiers may be built with contemporary commercial transistors.

Conclusions

It was demonstrated that a high-accuracy amplifier may be realized by having a relatively low loop gain, provided the variation of the loop gain can be kept small. Since a high loop gain is not easily realizable with the transistors available for this investigation, it was imperative that the amplifier gain variations be minimized. This was accomplished by local current and voltage feedback or self-feedback. For the transistors used it was shown that self-feedback is a satisfactory means of reducing gain and terminal impedance variations. As a consequence of self-feedback, the gain and terminal impedances may be rather accurately computed with the use of manufacturers' data and the equations of Table I. Further, for a-c amplifiers, the undesirable effects of temperature are partially overcome by the self-feedback action. Self-feedback does not reduce the high-frequency phase shift of the transconductance. This phase shift must therefore be considered as the most important factor limiting the maximum available loop gain.

Discussion

W. M. Grim, Jr. (General Electronics Laboratories, Inc., Cambridge, Mass.): The author has presented an excellent solution to the problem of designing a transistor amplifier with the gain stability which is required for computer use. The use of local feedback not only reduces the amount of over-all feedback necessary to maintain the required gain stability, but also reduces the effects of the transistor parameter variations on the feedback-loop stability.

The use of self-feedback techniques, together with circuits for stabilizing the operating conditions, may make the use of over-all feedback unnecessary, in applications where the gain stability requirements are less stringent.

Rating and Application of Germanium and Silicon Rectifiers

F. W. GUTZWILLER
ASSOCIATE MEMBER AIEE

GERMANIUM and silicon P-N junctions are becoming well known for their very nearly ideal combination of efficiency, flexibility, and reliability factors. Despite their high efficiency, the small internal losses of this type of rectifier cell are the chief criterion for rating and application.

The heart of a semiconductor rectifier is the P-N junction. In a philosophy analogous to that employed in rating practically every other type of electrical power device, the temperature rise of this P-N junction governs the successful application of the rectifier cell. Long life and high reliability can be expected if junction temperature is limited to a reasonable value under continuous duty conditions, and if an ample safety margin is maintained for unusual voltage and current transients that may be expected in service.

The temperature at which a junction may satisfactorily operate depends to a great extent on the design and fabrication of the rectifier cell. High temperatures promote chemical activity of contamination on the delicate and minute surfaces of the junction. This chemical activity deteriorates the voltage-blocking ability of the rectifier to the eventual point where breakdown or thermal runaway occurs.

Two obvious alternatives, or a combination of both, can protect the junction from this possibility. One is to limit junction temperature to such a low value that chemical activity is reduced to a negligible rate. The other, and more direct, approach eliminates the contaminating foreign agents from possible contact with the junction. This can be accomplished by extreme care in fabrication, chemical or electrolytic etching of the junction, rigorous cleaning processes (all to rid the device of initial contamination), and finally, a hermetic seal to keep subsequent environmental contamination away from the junction during the life span of the cell. Careful attention to these cleanliness factors permits trouble-free operation at junction temperatures in excess of 100 degrees centigrade for germanium cells and well over 200 degrees centigrade for silicon cells.

Heat Generation

The junction generates heat during the course of operation by virtue of two losses: voltage drop across the rectifier while it is conducting in the forward, or easy current-flow, direction; and leakage current through the cell when it is restraining the flow of load current in the reverse, or blocking direction. The forward voltage drop for a typical germanium rectifier cell for various load currents and junction temperatures is shown in Fig. 1. The leakage or reverse current for various reverse voltages and junction temperatures is shown in Fig. 2. The characteristic curves of silicon rectifier cells are similar in shape to those of germanium cells, differing primarily in over-all magnitude.

The heating of the junction for any particular forward current wave form, when averaged over a complete cycle, can by expressed as

$$P_f=\frac{\int_0^T v_f i_f dt}{\int_0^T dt} \tag{1}$$

where

P_f = average forward heating power
i_f = instantaneous load current, determined by input voltage wave form and circuit impedance
v_f = instantaneous forward voltage drop corresponding to i_f
T = period of one cycle

The average heating due to reverse voltage across the junction can be expressed as

$$P_r=\frac{\int_0^T i_r v_r dt}{\int_0^T dt} \tag{2}$$

where

P_r = average reverse heating power
v_r = instantaneous reverse voltage, determined by input voltage wave form
i_r = instantaneous leakage current corresponding to v_r and operating junction temperature

It is possible to solve both of these equations using suitable analytical approximations for the voltage-current relationships shown in Figs. 1 and 2, provided the voltage supply and load current wave shapes can be represented by simple mathematical expressions. As an alternative, satisfactory solutions for heating power can be attained by graphically integrating the instantaneous product of forward current and forward voltage drop, and reverse current and reverse voltage, for the wave shapes of the application. For even extremely distorted voltage and current wave shapes, completely satisfactory approximations can be made by dividing the wave shape up into ten or less equivalent-area sections in bar-graph fashion.

Total average heating at the junction (P_t) is the total of forward and reverse heating:

$$P_t=P_f+P_r \tag{3}$$

Silicon rectifiers, which have a substantially lower reverse current and a higher forward voltage drop than germanium rectifiers of equal power rating, have so little reverse heating compared to forward heating that P_r may be considered negligible in many cases.

Heat Dissipation

Fig. 3 is a cross section through a typical semiconductor power rectifier of the type shown in the 4-fin stack arrangement of Fig. 4. The P-N junction is soldered to a copper stud, which is in turn mounted on a radiator or cooling fin. This mechanism affords a highly conductive path to the cooling fin for the heat generated at the junction. The fin liberates this heat to the surrounding medium by radiation, convection, and conduction.

The flow of heat from the junction to a reference point on the fin, under stable conditions, can be expressed as

$$P_t=K_j(T_j-T_f) \tag{4}$$

where

K_j = thermal conductance between junction and fin
T_j = temperature of junction
T_f = temperature of fin

Likewise, the flow of heat from cooling fin to the surrounding ambient can be expressed as

$$P_t=K_f(T_f-T_a) \tag{5}$$

where

K_f = thermal coefficient of heat transfer between fin and ambient
T_a = temperature of ambient

Paper 56-934, recommended by the AIEE Metallic Rectifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 1–5, 1956. Manuscript submitted June 1, 1956; made available for printing July 20, 1956.

F. W. Gutzwiller is with the General Electric Company, Clyde, N. Y.

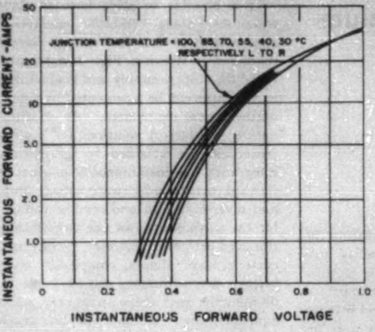

Fig. 1 (left). Forward characteristics of a typical semiconductor rectifier cell

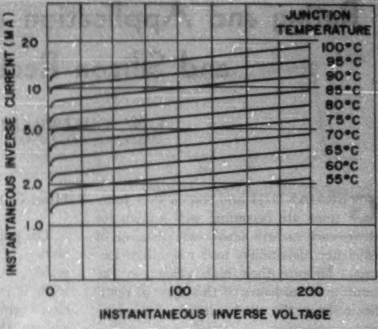

Fig. 2 (right). Reverse characteristic of a typical semiconductor rectifier cell

Combining these two equations to eliminate T_f, and introducing equation 3, gives

$$P_t=K_{eq}(T_j-T_a)=P_f+P_r \qquad (6)$$

where

$$K_{eq}=\frac{K_jK_f}{K_j+K_f}$$

This equation permits solution for the temperature rise between ambient and junction as a function of heating losses at the junction. Typical temperature rises for various cooling conditions (varying K_f), as a function of heating, are shown in Fig. 5. The preponderant effect of radiation when the rectifier is not forced air-cooled causes the curves for free convection air conditions to curve slightly from the linear form.

Rating the Cell

If this type of cooling curve, together with voltage-current characteristics and recommended junction operating temperatures, is available for a device, the equipment designer has the basic information for determining the continuous-duty operating temperatures of the rectifier junction under any conditions. Conversely, he has the data necessary to determine how many cells, and in what configuration he must arrange them, to achieve his load voltage and current requirements.

For commonly encountered types of voltage and current wave shapes, the device manufacturer usually publishes forward current ratings determined in the foregoing manner for various ambient temperatures and velocities of cooling air. A set of such curves for a cell used in a single phase sine wave voltage supply is shown in Fig. 6. Operation at any point of these curves develops the same junction temperature. Peak inverse voltage is maintained constant throughout.

In multiphase rectifier circuits, conduction of forward current through each leg is reduced to a shorter part of the whole cycle than in single-phase circuits, e.g., 120 degrees in an ideal 3-phase circuit. To attain the same average forward current, the cell must conduct instantaneously at a higher level. Since instantaneous heating increases at a rate proportionately greater than the increase of instantaneous forward current, the rectifier cell develops more average forward heat when operating in multiphase circuits. During the inverse part of the cycle, the cell must block voltage for two-thirds of the cycle in three phase, for example, instead of only one-half cycle as in single phase. For the same peak inverse voltage the 3-phase circuit will therefore develop additional reverse heating in the cell. Because of this more severe heating during conduction and blocking, semiconductor cells are usually derated for multiphase circuits, sometimes quite drastically.

Intermittent Duty

The foregoing approach determines the continuous-duty rating of a rectifier cell by calculation of the temperature rise between ambient and junction after power has been applied to the cell for an indefinitely long period of time. If, on the other hand, power is applied to the cell intermittently, transient heating occurs as heat is stored in, and then released from, the thermal capacity of junction, mounting, and cooling fin.

Essentially two temperature transients occur. If a cell is energized after having been allowed to stabilize at ambient temperature under no load and no voltage, the semiconductor junction very quickly ascends to its stable temperature rise above the cooling apparatus, in accordance with equation 4. This usually occurs in a matter of cycles, depending mainly on the thermal mass immediately surrounding the junction of the device, and the thermal conductance to the heat sink of the cooling apparatus.

The cooling system, which has a much larger mass than the junction, heats much more slowly, and may take as long as an hour to stabilize at its ultimate differential temperature above the ambient, in accordance with equation 5.

When a cell is de-energized, the junction temperature descends to the heat sink temperature within a few cycles. The heat sink, however, drifts only gradually down to ambient temperature as it releases its substantial amounts of stored heat to the cooling medium.

Depending on the application, both of these heating transients may be utilized to develop substantial improvements over continuous-duty ratings for intermittent types of operation, such as circuit-breaker closing and hoist drives. A circuit-breaker closing application demands rectified current for only the few cycles required to close the breaker. The cooling fin acts as a true heat sink in this case, and very large currents can be rectified by taking advantage of the short-term thermal capacity of the junction. A hoist drive, on the other hand, requires power a good deal longer than a few cycles, but it still can be considered an "on-off" type of load. In this case, the cooling fin has time to store substantially more heat while the load is imposed, and its temperature may rise considerably, but still a good deal less than if allowed to reach its stable temperature under continuous load. The magnitude of allowable loading for various duty cycles may be determined quite readily by analytical approaches.

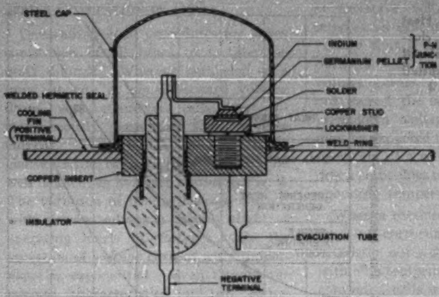

Fig. 3 (left). Cross section of a medium-power germanium rectifier cell

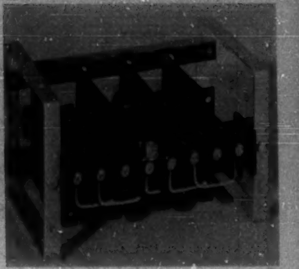

Fig. 4 (right). Typical rectifier stacking arrangement. Cooling fins are 3½ inches square

Thermal Stability

In well-fabricated germanium rectifier cells, the variation of reverse heating for junction temperatures within the normal operating range and for a fixed reverse voltage can be empirically represented by this equation

$$P_{rj} = P_{ra}\epsilon^{\gamma(T_j - T_a)} \tag{7}$$

where

P_{rj} = reverse heating at junction temperature T_j
P_{ra} = reverse heating with junction at ambient temperature T_a
γ = constant of temperature variation
ϵ = base of natural logarithm

This equation is plotted in Fig. 7. The heat generated by a specified forward current is relatively independent of junction temperature, dropping only slightly as the temperature is raised. This variation P_f is also plotted in Fig. 7, and is added to the reverse heating to yield total junction heating P_t. The equation of the total heating curve, considering forward heating constant with temperature, is

$$P_t = P_f + P_{rj} = P_f + P_{ra}\epsilon^{\gamma(T_j - T_a)} \tag{8}$$

The origin of the abscissa of Fig. 7 is the ambient temperature of the application. From this point, following the locus of equation 6, can be laid out the heat-dissipating characteristic of the rectifier.

When the rectifier cell is energized in the circuit, the junction will heat as defined by the heat generation curve, and will cool as defined by the heat dissipation curve. The junction temperature will rise to the point where heat generation exactly matches heat dissipation. This occurs where the two curves intersect. The area enclosed by the two curves is a rough measure of the inherent stability of the application.

If junction heating is increased by additional voltage or current, or by raising ambient temperature, or if cooling is reduced, the overlap of the two curves decreases, and, if taken to extremes, the two curves fail to intersect. Under these conditions, the rectifier cannot stabilize thermally. The temperature of the cell increases to the melting point of the junction or to the point where thermal stress causes cell failure. This action is called "thermal run-away."

An analytical solution for the critical operating point at which thermal run-away becomes imminent can be derived for a rectifier that meets the conditions of equations 6 and 8.

$$P_{ra\,\max} = \frac{K_{\theta a}}{\gamma}\epsilon^{-\left(1+\frac{\gamma P_f}{K_{\theta a}}\right)} \tag{9}$$

This critical value of reverse heating is measured with the junction at ambient temperature, the most readily available reference point. In actual application, substantial safety factors are usually applied to this critical value to allow for overloading, surges, and transient conditions, and for possible variations in the reverse characteristic of the rectifier cell due to contamination. Because of their inherently higher reverse heating, thermal stability criteria are usually of more importance and interest for germanium rectifiers than for silicon devices.

Some Circuit Design Considerations

Fusing

Under load fault conditions, as well as during rectifier faults, many times normal current flows through the cells. The resulting current densities are much higher than normal, and heating of the junctions becomes severe. Due to the limited thermal capacity of a junction, temperature rises quickly. Under conditions where circuit impedance is extremely low, very high fault currents result, and junction temperature may rise to the breakdown point within a half-cycle. To safeguard rectifiers under these circumstances, additional circuit impedance in the form of high transformer reactance or lumped inductance or resistance can be introduced to the circuit to limit fault current to the rectifier surge rating recommended by the manufacturer, until circuit protection can function. As a satisfactory alternative where voltage regulation requirements do not tolerate introducing extra impedance, current-limiting fuses can be used. These devices can open the faulted circuit in less than one-quarter cycle, before current can rise to its peak value and destructive proportions.

Surge Voltage Protection

When a semiconductor rectifier feeds an inductive load from a highly reactive a-c line, special protection against induced voltage surges may be necessary. Under these conditions, the rectifier cell conducts an essentially square wave of current. When the cell suddenly commutates its load to the next leg, a charge of current carriers are left stranded in the bulk semiconductor material. These carriers, known as "holes," normally disappear by recombination with electrons or by diffusion out of the semiconductor material. However, when reverse voltage is applied to the cell immediately after heavy forward current conduction, these carriers do not have time to recombine and diffuse naturally, but are instead swept across the junction into the P region, resulting in a current limited only by circuit impedance. Until the carriers have been completely swept out of the bulk semiconductor, the resistance of the cell is very low, acting almost like a short circuit.

Within a few micro-seconds after reverse voltage has been applied, the carriers have all been swept out, and the cell recovers abruptly. Its resistance immediately changes from a fraction of

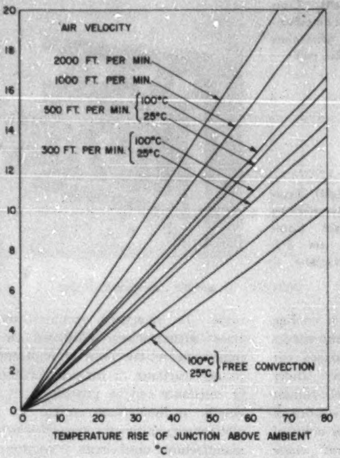

Fig. 5 (left). Heat dissipation characteristics of cell type illustrated in Fig. 4

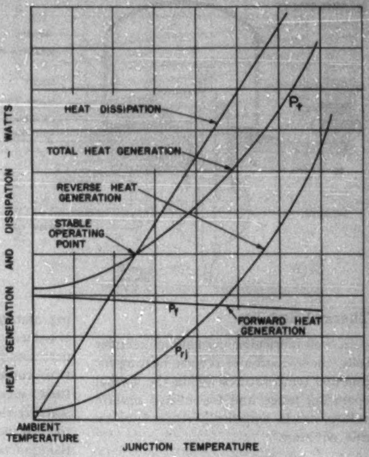
Fig. 7 (right). Thermal characteristics of a rectifier cell under constant load and voltage conditions



an ohm to thousands of ohms, causing a substantial voltage surge to be induced in the line reactance. Particularly since this is a cyclical occurrence, it is important to protect the cells from these voltages if they are excessive. A few microfarads of capacitance installed across the a-c input terminals of the rectifier are usually sufficient to dampen the most vicious voltage spikes to values within rectifier capabilities, even in very high current installations.

A similar type of voltage surge may occur if fuses are used in individual legs of a rectifier circuit. In this instance, the voltage spike is not cyclical, but is generated in the line reactance when a fuse suddenly interrupts a high fault current. Here again, a small amount of capacitance across the a-c rectifier terminals will safeguard the cells from excessive voltage. Likewise, capacitors may be necessary to afford protection against line reactance voltage surges when load switching causes abrupt changes of current in the line reactance.

Paralleling Cells

The forward voltage-current relationship depicted in Fig. 1 illustrates the wide variation in forward current with relatively small changes in forward voltage drop. When cells are paralleled for higher current capacity, the voltage across the cells is necessarily equal, and it follows that the characteristics of the cells must be extremely well matched if they are to share current reasonably well. For this reason, the cell manufacturer usually prefers to perform this matching operation in his factory. To maintain equal current-sharing throughout the operating range of current and temperature, and under fault conditions, connections between cells must have equal resistance and be symmetrical, and connector length, cross section of wire, and type of connecting lugs should be maintained as nearly equal for each parallel branch as is practicable. Fig. 8 illustrates an effective manner of connecting cells or stacks in parallel.

This circuit can be used for adequately paralleling up to six or more matched cells; however, it is not the ultimate for current sharing. Further improvement can be made by bringing the external leads to the center cell on each of the respective stacks.

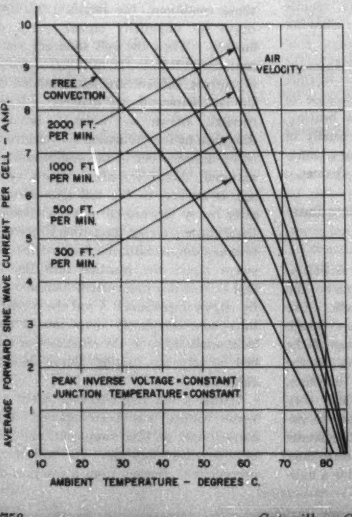


Fig. 6. Constant junction temperature ratings of a germanium rectifier cell

SERIES CONNECTION OF CELLS

Generalization of procedures for series connection of all types of rectifiers is quite difficult. Whereas paralleled cells must operate at equal forward voltage drops, series-connected cells must instantaneously pass the same reverse current. The reverse voltage-current characteristic of a rectifier cell can be well defined, as has been shown in Fig. 2. The variation of reverse leakage current with reverse voltage is usually slight at operating levels of voltage, while the variation of leakage current with temperature is exponential. Even though the reverse characteristics of two series-connected cells may be matched perfectly at the same junction temperature, a difference in junction temperature of only a few degrees will cause a grossly unequal distribution of voltage between the cells. Such a temperature variation must be expected in practical installations.

In some devices, depending on their application, the reverse heating of the cell is a large part of the cell dissipation. Under these conditions, substantial equalization of voltage between series-connected cells will be achieved, due to thermal self-correction. The cell that tends to assume a larger share of the voltage will heat up accordingly. Its reverse leakage current will tend to increase but, being limited by the other cells in series, the cell must decrease its share of the reverse voltage to normal values.

Other rectifier devices, particularly of the silicon type, exhibit a sharp nondestructive breakdown in reverse current at excessive voltage. This mechanism imposes an inherent limit on the reverse voltage that a cell can assume from its partners. As long as the total reverse voltage across all cells in series does not exceed the sum of their respective breakdown voltages, reliable operation may be expected from the cells, provided operation of a cell at, or near, its breakdown point does not exceed its maximum operating temperature limits.

When a rectifier cell exhibits neither a large self-correcting reverse heating characteristic, nor a sharp reverse breakdown within its temperature capabilities, series-connected cells will show substantial inequality in voltage distribution. To determine the effect of higher-than-normal reverse voltage on cell reliability, comprehensive life testing was conducted on medium power germanium rectifiers. For this particular type of device, no adverse effects were experienced on series-connected cells across which higher-than-rated peak inverse voltage was developed. The average peak inverse voltage across the cells in each leg was maintained at the normal cell rating. On the basis of these data, voltage-equalizing resistors, which had previously been used, were eliminated from circuits using medium power rectifier cells connected in series.

In a test to develop further information on this type of operation, medium power germanium rectifier cells were installed in three legs of the high-voltage power supply of a 50-kw short-wave transmitter. The circuit supplies 11,700 volts direct current and about 12.5 amperes under peak modulation. Forty-two germanium rectifier cells are connected in series in each of the three legs of the circuit with no attempt to ensure inverse voltage-sharing except matching of the reverse characteristics of the cells. The average peak inverse voltage of 293 volts per cell exceeds the nominal rating of the cells by approximately 45 per cent. In the 3 months to date that this test has been operating, the circuit has functioned without any incident in spite of the large overvoltage on the cells. It is felt that germanium and silicon will bring new standards of reliability and long life to this type of high-voltage d-c power supply.

A Method of Designing Small Power Transformers for Communication Equipment

HUBERT S. SEAR
NONMEMBER AIEE

A SIMPLE METHOD is presented for the design of a power transformer which does not require any trial-and error-calculations. Optimum wire gauges for each winding to minimize losses, and optimum cores made of commercially available laminations, can be easily obtained. The method is suitable for power transformers operating at any frequency where stray capacitative and inductive effects are negligible, having one or more secondary windings, and rated up to 500 volt-amperes.

Briefly, the window area, taken by each winding, is determined in terms of a factor K and one variable, N_p, the number of primary turns. The core cross-sectional area is also determined in terms of the factor k_p and of N_p. The product of these two factors determines the product of core cross-sectional area and window area. The derivation of this is shown in the appendix. Optimum core dimensions and lamination sizes are then selected from a nomogram on the basis of K and k_p.

Wire gauges can be selected easily which allow allocation of equal window area to primary and secondaries, thus minimizing copper losses. An actual example will serve to illustrate the design procedure, after which the condensed instructions in the summary should suffice for practical use.

EXAMPLE

Design a transformer to the following ratings.

Core Material: Allegheny Ludlum transformer *A*

Primary: 115 volts, 60 cycles

Secondary:

No.	Volts	Amperes	Volt-Amperes
1	640	0.150	96
2	5	3.0	15
3	6.3	3.0	18.9
			129.9

Insulation: 5-volt winding insulated for 1,300 volts to core

Current density: 1,000 circular mils per ampere

PROCEDURE

1. Estimated losses, 14 volt-amperes. Total volt-ampere rating 129.9+14=143.9 or 144.

2. Evaluate k_p for this transformer.

$$k_p=\frac{E_p\times 10^{-8}}{4.44\,fB_{max}k_{sf}}$$

where

E_p = primary voltage, 115 volts
f = frequency, 60 cycles
B_{max} = maximum flux induced in core. For Allegheny Ludlum transformer-grade silicon-steel laminations 70,000 lines per square inch is feasible
K_{sf} = stacking factor of laminations, 0.90
$k_p = 686$

3. Evaluate K for this transformer.

$$K=\frac{1}{t_p}+\frac{k_{s1}}{t_{s1}}+\frac{k_{s2}}{t_{s2}}+\frac{k_{s3}}{t_{s3}}$$

K_s = factor due to each secondary winding $=\frac{\text{secondary voltage}}{\text{primary voltage}}\times$ regulation (estd.)

$$k_{s1}=\frac{640}{115}\times 1.05=5.85$$

$$k_{s2}=\frac{5}{115}\times 1.10=0.0478$$

$$k_{s3}=\frac{6.3}{115}\times 1.10=0.0603$$

T_p = turns per square inch (including layer insulation) in primary

T_s = turns per square inch (including layer insulation) in each secondary

Evaluation of these factors requires selection of wire gauge to be used. This is done as in conventional designs, on the basis of current density desired, (circular mils per ampere).

$$\text{Primary current }\frac{144\text{ volt-amperes}}{115\text{ primary voltage}}=1.25\text{ amperes}$$

	Required Circular Mils	Wire Gauge to Be Used, No.
Primary	1,250	19
Secondary:		
1	150	28
2	3,000	15
3	3,000	15

Table I shows turns per square inch including paper layer insulation sufficient to support the wire. This wire table also shows the reciprocal of turns per square inch for easy substitution in the equation to evaluate K.

Primary *1:* $\frac{1}{T_p}$ $19.57\times 10^{-4}\times 1 = 19.57\times 10^{-4}$

Secondary *1:* $\frac{k_{s1}}{T_{s1}}$ $2.41\times 10^{-4}\times 5.85 = 14.10\times 10^{-4}$

Secondary *2:* $\frac{k_{s2}}{T_{s2}}$ $46.08\times 10^{-4}\times 0.0478 = 2.20\times 10^{-4}$

Secondary *3:* $\frac{k_{s3}}{T_{s3}}$ $46.08\times 10^{-4}\times 0.0603 = 2.78\times 10^{-4}$

$K = 38.65\times 10^{-4}$

4. The product of $K\,k_p$ would now be obtained and used on Fig. 1. However, since so many transformers are designed for 115-volt 60-cycle operation and use 4 per-cent silicon-steel cores, the nomogram in Fig. 2 has been developed requiring only evaluation of K. This limitation also allows inclusion of a scale on the nomogram giving the number of turns in the primary winding (N_p). The nomograms relate the core dimensions to k or $K\,k_p$. A_t is the total window area available for windings leaving insulation space indicated in Fig. 3. A_c is the cross-sectional area of the core. N_p is the number of primary turns. Optimal transformers have a square-core cross section and have the window completely filled.

Some commonly used lamination types are indicated on the nomograms by lines connecting their available window area with the cross-sectional area resulting in a square center leg. Therefore, if a square cross section is desired for a particular $K\,k_p$ value (or K value), a ruler is rotated about this value on the K scale until it intersects the A_c value for one of the lamination types. The intersection of the ruler with the A_t scale will give the window area required for the transformer. If this window area exceeds that available in the lamination type chosen on the A_c scale, this lamination type will not be suitable when a square center leg is used. The ruler is then rotated about the same point on the K or $K\,k_p$ scale until either

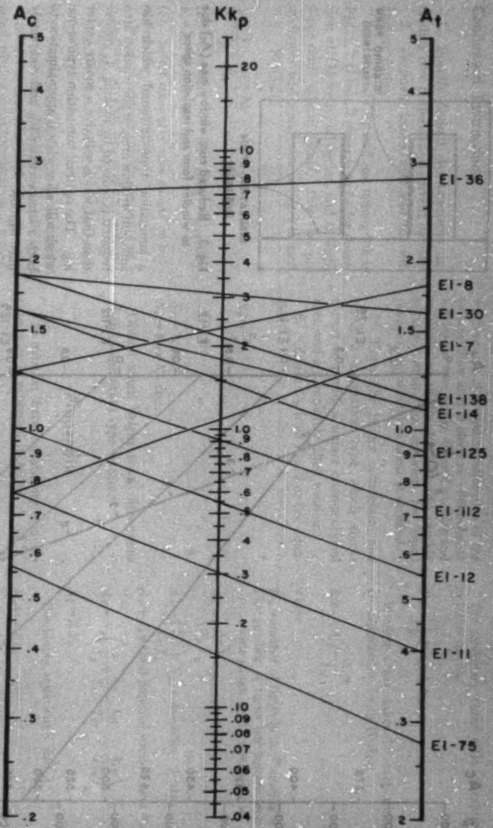

Fig. 1. Universal core selection nomogram

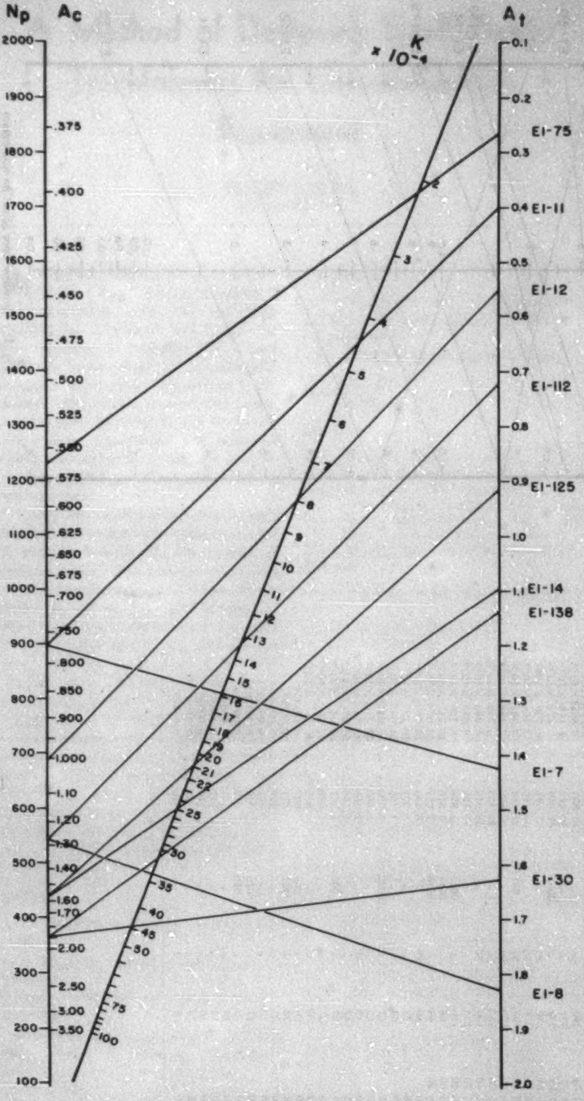

Fig. 2. Special core selection nomogram

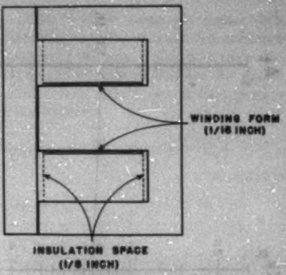

Fig. 3. Reduced core window area (A_t) due to winding form and insulation space

a lamination type is found which has sufficient window area, or the window area required is reduced by making A_c greater than that which will give a square center leg. The optimal lamination type is one which will allow closest approximation to both a square center leg and completely filled window.

By entering the nomogram in Fig. 2 at $K=39\times10^{-4}$ it is found that the line for lamination-type *EI-30* lies very close. However, if a square cross section at 1.90 square inches is taken, the window will not be completely filled, while a completely filled window (with useable area of 1.62 inches) will not allow a square cross section for the core. The nomogram allows selection of the optimal combination. It should be observed that, although the core cross-section area can be varied above and below the value indicated by the intersection of the lamination line with the A_c scale by varying the stack height, the window area A_t available is not so flexible. The value, indicated on the nomogram, may be exceeded only slightly at the expense of insulation spaces, marked in Fig. 3.

Taking the window area, which would be filled as 1.6 square inches, a core cross-sectional area of 1.7 square inches about 410 primary turns is obtained. Window space has been left for the high-voltage insulation around secondary 2. Then secondary turns are obtained from Np and k_s ($N_s=k_s\times N_p$)

Secondary *1:*	$5.85\times410=2{,}400$
Secondary *2:*	$0.0478\times410=19.6$ or 20
Secondary *3:*	$0.0603\times410=24.7$ or 25

Stack height is obtained by dividing the area obtained, by the center leg width given in Allegheny Ludlum Steel Corporation catalog *EM3* for lamination type *EI-30*.

$$\text{Stack height}=\frac{1.70}{1.375}=1.24 \text{ inches}$$

Condensed Instructions

1. Specify desired characteristics, including core material and current density.

2. Estimate losses, and add to volt-ampere rating.

3. Evaluate k_p, and use nomogram in Fig. 1. If transformer is to be for operation at 115 volts, 60 cycles, and utilizing 4-per-cent silicon steel, this is not necessary and nomogram in Fig. 2 is used.

4. Evaluate

$$K=\frac{1}{T_p}+\frac{k_{s1}}{T_{s1}}+\frac{k_{s2}}{T_{s2}}\cdots\cdots\frac{k_{sn}}{T_{sn}}$$

(*a*). Evaluate k_s for each secondary. $k_s=E_s/E_p\times$regulation.

(*b*). Select secondary wire gauges on basis of desired current density.
Calculate primary current (=total volt-amperes divided by primary voltage), and select required wire gauge.
Obtain reciprocal of turns per square inch from wire table.

(*c*). Substitute results of steps (a) and (b) to obtain value of K. It should be noted that losses are minimized by allocating equal window areas to primary and secondary windings. Since each fraction in the equation for K represents the relative window area of a winding, allocation of the total window area is obvious. Selection of a different wire gauge for one winding and recalculation of the fraction will quickly indicate when the criterion for equal primary and secondary areas is satisfied.

5. Enter the proper nomogram, and select a lamination type which comes closest to giving a square cross-sectional area and a completely filled window.

6. Obtain N_p from Fig. 2 or the equation

$$N_p=\frac{k_p}{A_c}$$

Obtain

$$N_{s1}=k_{s1}\times N_p$$
$$N_{s2}=k_{s2}\times N_p \text{ etc.}$$

Obtain stack height from dimensions of the lamination type selected.

Appendix

The relation between primary winding quantities is expressed in terms of N_p.

$$N_p=\frac{E_p\times 10^{-8}}{4.44fB_{max}\,AcK_{sf}}=\frac{k_p}{A_c} \tag{1}$$

The secondary turns ratio is expressed in terms on N_p.

$$N_s=\frac{Es}{Ep}N_p r=k_s N_p \tag{2}$$

Window areas, taken by each winding, are expressed in terms of N_p.

$$\text{Area}=A_n=\frac{N_n}{T_n} \tag{3}$$

where

N_n = number of turns in any winding n
T_n = number of turns per square inch for wire gauge used in winding n

$$A_p=\left(\frac{N_p}{T_p}\right)=\text{primary area}$$

$$A_{s1}=\left(\frac{k_{s1}}{T_{s1}}\right)(N_p)=\text{secondary } 1 \text{ area}$$

$$A_p+A_s=\text{total required window area}=A_T$$

$$A_T=N_p\left(\frac{1}{T_p}+\frac{k_{s1}}{T_{s1}}+\frac{k_{s2}}{T_{s2}}\cdots\frac{k_{sn}}{T_{sn}}\right)$$

$$A_T=KN_p$$

Combining equations 1 and 3

$$A_cA_t=Kk_p \tag{4}$$

The nomograms allow easy solution of this equation.

Accurate Determination of the Capacitance of a Thin Rectangular Plate

DANIEL K. REITAN
MEMBER AIEE

THOMAS J. HIGGINS
MEMBER AIEE

THE PURPOSE of this paper is two-fold: to determine by the method of subareas the charge distribution and capacitance of a rectangular area; and to advance therefrom a universal curve which furnishes accurate values of the capacitance of a rectangular area of any specified dimensions. From well-known theory, rigorous determination of these electrical quantities hinges on determination of the corresponding electrostatic potential function V. However, determination of the function for a specified plane area is of such mathematical difficulty that solution to date has been achieved for only one plane area, the elliptical disk of which the circular disk is a special case. In consequence, explicit equations for the charge distribution and electrical capacitance are known only for these two plane areas. However, need of accurate knowledge of the capacitance of a rectangular plane area, or of a certain parameter[1] equal in magnitude to the capacitance, occurs in numerous physical problems. (Thus, the normal force R on a thin rectangular plate moving in the direction of its normal with a velocity V through a liquid of viscosity μ is $R=8\pi\mu CV$, where C is a parameter equal to the capacitance of a rectangular planar conductor of the same dimensions as the thin plate.) To cite an example of much current interest in electrical engineering, a knowledge of the capacitance of rectangular plates is required in the rational design of grounding systems for high-voltage power systems.[2–4] Accordingly, it is obviously most desirable to have in hand curves which readily afford values of the capacitance with accuracy sufficient for design purposes. Precisely such a set of curves is advanced in this paper, the essential content of which may be summarized as follows: The method of subareas, earlier formulated and used by the authors to obtain excellent approximate solutions of the difficult, long-standing problems of determination of the capacitance and charge distribution of a plane annulus[5] and a cube,[6,7] is recast to enable solution of the present problem. Therewith equations for the capacitance and charge distribution of an arbitrarily dimensional rectangular area are formulated; and the solutions of these equations, as effected through use of International Business Machines equipment, are then utilized to plot a universal curve of capacitance versus width/height from which can be read the capacitance of any specified rectangular area with sufficient accuracy for most design purposes. Corroborative of the correctness of the solution in general, this curve falls within the narrow upper and lower bounds to be calculated from the known expressions for the capacitances of the circumscribed and

inscribed ellipses. Finally, comparison of this universal curve with the corresponding curve plotted from Howe's[3] well-known and much used expression for the approximate capacitance of a rectangular area reveals that this expression yields values in considerable error over much of the range of w/h (width/height).

Basic Theory of Calculation

The basic theory of the determination of capacitance and charge density distribution by the method of subareas is detailed in references 5 and 6. Accordingly, it suffices here to recapitulate the essential steps of calculation. First, the particular area under consideration is divided into geometrically identical subareas, sufficiently small that the charge density is substantially constant over them and of such shape that the potential produced at any arbitrary point by a uniformly charged subarea can be calculated without too great difficulty. Second, at the same geometrically located point in each subarea the potential V_i due to its own charge and to the charges on the other subareas, assumed uniformly distributed over these subareas, is calculated. Taking into account any symmetry present in the subdivision, the procedure yields a set of n linear algebraic equations in terms of the n unknown charges on the subareas. Third, paralleling the known condition that the potential is the same on each subarea when the charge distribution is in equilibrium, the potential V_i on each subarea is set equal to V_0. Fourth, solution of the resulting set of n linear algebraic equations yields the charge on each subarea, as expressed in terms of the equipotential V_0. Fifth, summing these charges on each subarea yields the total charge Q, expressed in terms of V_0. Sixth, approximate numerical value of the capacitance is calculated from $C \cong Q/V_0$. Obviously, the approximate distribution of charge is afforded by the known values of the charges of the subareas.

The capacitance and charge density can be obtained to a high degree of accuracy by taking subareas sufficiently small in size. Of course, the labor involved in solving the set of n linear equations increases rapidly with n. However, as evidenced by the illustrative examples of this paper, surprisingly accurate values of capacitance and charge distribution can be obtained with use of small n, particularly if the area in question possesses symmetry about one or more axes.

Determination of Capacitance of a Thin Rectangular Plate

As a first approximation to calculation of the capacitance of a rectangle (thin rectangular plate) consider a charge distribution as in Fig. 1: the charge density is assumed constant over the surface of the rectangle. Then as detailed in Appendix I, the approximate value of capacitance to be computed with this distribution is $C = 0.597 \mu\mu f$ (micromicrofarad) for a rectangle of 3 by 1 cm (centimeters). The charge density, as used here, is the sum of the equal charge densities at corresponding points on the two opposite sides of the thin plate, hence twice the actual charge density on one side. In that the problem under discussion is one of absolute electrical measurement, it is convenient to work in unrationalized centimeter-gram-second units. Accordingly, the units of all quantities mentioned are in this system, except as specifically noted otherwise.

As a second approximation to calculation of the capacitance of a 3 by 1 cm rectangle, consider a charge distribution as in Fig. 2, comprising a 9 by 3 rectangle subdivided into 27 uniformly charged subareas. A well-known theorem in electrostatics states that the ratio of the capacitances of two geometrically similar areas is equal to the ratio of the corresponding linear dimensions. Thus, the capacitance of the 9 by 3 rectangle is three times that of the capacitance of a 3 by 1 rectangle. Appreciation and use of this theorem enables employment of the unit square as the basic subarea, with consequent simplification of numerical computation.

Consideration of symmetry limits the number of unknown q_i to ten. The potential V_a at the center of subarea A_a is comprised of a component of potential contributed by the charge q_a itself plus components contributed by each of the remaining subareas. Now, as detailed in Appendixes I and II of reference 6, the potential at the center of a unit subarea due to its own charge of uniform density q is 3.52549 q; and the potential at the center of a unit subarea due to the uniform

Vol. 7

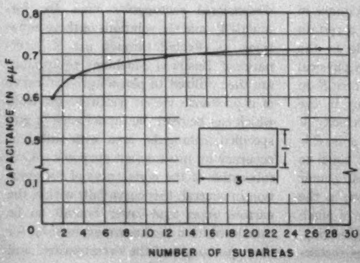

Fig. 3 (left). Capacitance of 3 by 1 cm rectangle as function of number of subareas

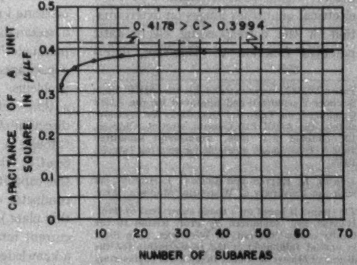
Fig. 4 (right). Capacitance of unit square as function of number of subareas



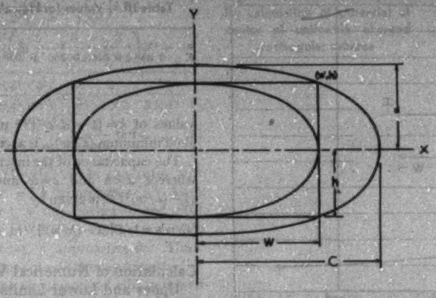


Fig. 5. Co-ordinates for calculation of upper and lower limits of capacitance of rectangle

density q' on any second subarea is well approximated by q'/d, where d is the distance between their centers.

Utilizing these relationships to determine the total potential at the center of a subarea of charge density q_a, and performing the necessary arithmetic, yields the first of the set of equations of Appendix II for the 9 by 3 rectangle. Proceeding similarly for subareas b through m yields the remaining equations. It follows from the geometric symmetry of the rectangle that the coefficients k_{ij} and k_{ji} $(i \neq j)$ either should be equal or one should be twice or four times the other. The corresponding coefficients of the set of equations satisfy these conditions. Next, imposing the condition that all V_i equal V_0, and solving the resulting set of equations, yields the numerical values tabulated in Appendix II. In return, these yield the associated approximation Q_t to the total charge Q on the plate as

$$Q_t = \sum_{i=a}^{m} q_i \text{ area}_i = 1.92797 V_0 \tag{1}$$

Accordingly, the corresponding approximation to the capacitance $C = Q/V_0$ of a 3 by 1 rectangle is

$$C \cong 1.92797 V_0 / 3 V_0 = 0.64265 \text{ esu} = 0.71405\ \mu\mu f$$

where esu is electrostatic units.

Fig. 3, which comprises a plot of the capacitance of a 3 by 1 rectangle versus the number of subareas used in obtaining a corresponding value, is evidence of the excellent accuracy gained by use of only 27 subareas and of the fact that only a small increase in accuracy is to be gained by use of more subareas.

Special Case of a Square

Similar calculation for the particularly interesting configuration of the square yields the convergence curve of Fig. 4. Extrapolation of the subarea values according to the method delineated by Allen and Dennis,[9] yields a limiting value $C = 0.4019\ \mu\mu f$. Corroboratively, this value is in essential agreement with the value of 0.40 $\mu\mu f$ given by Maxwell.[10,11] Also it falls within the limits of $0.4178 > C > 0.3994$ $\mu\mu f$, given by Polya and Szegö[12] through use of Schwarz's principle of symmetrization. It is of interest to note that the lower limit 0.3994 $\mu\mu f$ was rigorously derived by Lord Rayleigh; however, the upper limit is based on Polya and Szegö's conjecture that of all surfaces that can be enclosed by an outermost radius r, a circular plate of this same radius r has the maximum capacitance.

Limits on Possible Value of Capacitance of a Rectangle

As is evident from Fig. 4, application of the method of subareas to effect the approximate capacitance of the special case of the square yields fair accuracy on a basis of 16 increments and excellent accuracy on a basis of 36 increments. Correspondingly, it may be inferred that the solution of the 3 by 1 rectangle on a 12-increment basis is less than the exact value, whereas the solution on a 27-increment basis ought to be close to the exact value. Polya and Szegö's bounds ascertain the explicit accuracy of a subarea value for the square. On the other hand, inference as to the relative accuracy of the 27-increment subarea value for the 3 by 1 rectangle can only be conjectured in the absence of similar bounds for a rectangle. The obviously desirable effectance of these bounds will now be discussed.

Consider the rectangle and the corresponding inscribed and circumscribed ellipses of Fig. 5. By virtue of the well-known theorem in electrostatic theory which states that the capacitance of a conductor is greater than the capacitance of any part of it, it follows that the capacitance of the rectangle is greater than the capacitance of the inscribed ellipse and less than the capacitance of the circumscribing ellipse. Inasmuch as the dimensions of the rectangle fix the dimensions of the inscribed ellipse, the lower limit thus obtained is definitely fixed in value. On the other hand, ellipses of

various eccentricity can be circumscribed about the rectangle, whence determination of the minimum upper limit hinges on ascertaining the circumscribing ellipse having minimum capacitance. This latter can be obtained as follows.

The capacitance (see reference 10, page 237) of the circumscribed ellipse is $C=c/F(k)$ where c is the length of the major semiaxis, $k=[1-(d/c)^2]^{1/2}$ is the eccentricity, and $F(k)$ is the elliptical integral of the first kind with argument k. Inasmuch as the point (w,h) of Fig. 5 lies on the circumscribed ellipse whose equation is $(x^2/c^2)+(y^2/d^2)=1$, it follows that $(w^2/c^2)+(h^2/d^2)=1$. Multiplying each member by c and substituting $1-k^2=(d/c)^2$ yields $c^2=w^2+[h^2/(1-k^2)]$, whence

$$c=w[(1-k^2)+(h/w)^2]^{1/2}/(1-k^2)^{1/2} \qquad (2)$$

Substituting this value of c in $C=c/F(k)$ yields the capacitance of the circumscribing ellipse as

$$C=w[(1-k^2)+(h/w)^2]^{1/2}/(1-k^2)^{1/2}F(k) \qquad (3)$$

Dividing each side of equation 5 by w yields

$$(C/w)_c=[(1-k^2)+(h/w)^2]^{1/2}/(1-k^2)^{1/2}F(k) \qquad (4)$$

For a rectangle of specified ratio h/w, the ratio C/w for the circumscribing ellipse is a function of k alone. Hence, the value of k yielding the minimum value $(C/w)_{cm}$ of $(C/w)_c$ and thus of C when w is specified, can be found by the usual procedure for determining the minimum value of a function of one variable, i.e., differentiating $(C/w)_c$ with respect to k, setting the resulting expression equal to zero, and solving the equation thus formed for k_m. In that the equation which must be solved for k is a complicated transcendental equation involving elliptical functions, the simplest method of solving for the desired minimum value of $(C/w)_c$ is by substituting successive values of $k=[1-(d/c)^2]^{1/2}$ until the desired minimum $(C/w)_{cm}$ is ascertained.

The capacitance of the inscribed ellipse, whereof $d=h$ and $c=w$ and thus $k=[1-(h/w)^2]^{1/2}$, is given by

$$(C/w)_i=1/F\{[1-(h/w)^2]^{1/2}\} \qquad (5)$$

Calculation of Numerical Values of Upper and Lower Limits

When $w/h=1$, the rectangle is a square. The inscribed ellipse is a circle of radius $r=h=w$ and has a $(C/w)_i$ ratio of

$$(C/w)_i=1/F[(1-1)]=1/F(0)=1/1.571=0.637 \text{ esu}=0.708\ \mu\mu f \qquad (6)$$

This value, and other values of $(C/w)_i$ as determined by substitution of different w/h ratios in equation 5, are shown in Table I.

The values of $(C/w)_{cm}$, determined by successive substitution of various values of k in equation 4 for different w/h ratios, are also shown in Table I. It may be noted that the value for $w/h=1$, when the minimum circumscribing ellipse is a circle, is $(C/w)_{cm}=0.900$ esu $=1.00\ \mu\mu f$. Corroboratively, this value of 1.00 $\mu\mu f$ is in agreement with the value to be obtained from the well-known equation for the capacitance of a circular disc: $C=2r/\pi$. For in this case of $w=1$, the square is two units on a side, and the circumscribing circle is of radius $r=1.414$; whence $(C/w)=2.828/\pi=0.900$ esu $=1.00\ \mu\mu f$. The upper and lower limits for C/w when $w/h=2$, 4, 6, and 10, as shown in Table I, are obtained in similar fashion.

As the value of w/h becomes large (over 100), it is increasingly difficult to compute $(C/w)_{cm}$ by use of available numerical tables of elliptical functions. However, in this range the value of k is very close to unity and calculation is easily effected by use of the well-known series expansion[13] for $F(k)$

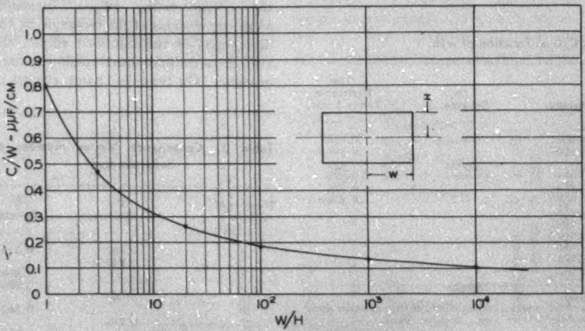

Fig. 7. Normalized curve of capacitance of rectangle

Table IV. Final Values for Universal Curve of Fig. 7

w/h	C/w	Basis for Computation
1	0.804	Subareas

10^3	0.133	$C/w \cong 1/(Ln\ 4w/h)$
10^4	0.104	$C/w \cong 1/(Ln\ 4w/h)$

$$F(k)=\ln\frac{4}{k'}+\frac{1^2}{2^2}\left(\ln\frac{4}{k'}-\frac{2}{1\times 2}\right)k'^2+\frac{1^2\times 3^2}{2^2\times 4^2}\left(\ln\frac{4}{k'}-\frac{2}{1\times 2}-\frac{2}{3\times 4}\right)k'^4+\frac{1^2\times 3^2\times 5^2}{2^2\times 4^2\times 6^2}\left(\ln\frac{4}{k'}-\frac{2}{1\times 2}-\frac{2}{3\times 4}-\frac{2}{5\times 6}\right)k'^6+\ldots \tag{7}$$

where $k'=(1-k^2)^{1/2}$. As the ratio w/h approaches ∞, k approaches 1. As k approaches 1, k' approaches 0, and $F(k)$ approaches $\ln (4/k')$. Further, as w/h approaches ∞, c approaches w. Thus, for large values of w/h the capacitance $C=c/F(k)$ of the circumscribed ellipse is well approximated from above by $C\cong w/\ln(4w/h)$. This is also the approximate value of the inscribed ellipse. Thus, for large values of w/h the upper and lower limits coalesce, both yielding an excellent approximation to the exact capacitance of the rectangle. Correspondingly, the values of C/w in Table I for ratios of $w/h>10^2$ are as computed from $C/w\cong 1/\ln(4w/h)$.

The curve of Fig. 6, plotted from the values of Table I, reveals at a glance the quality of the available limits on the possible value of the capacitance of a rectangle of specified ratio w/h. Also in Fig. 6 have been entered the nearly exact values of C/w for a square as cited, and for a 3 by 1 rectangle as calculated in Appendix II. On the basis of these points, it is to be concluded that the values of capacitance of rectangles of small w/h ratio are better approximated by the curves for the inscribed ellipse or for Rayleigh's lower limit than by the curve of averaged values of C/w for the circumscribed and inscribed ellipses.

Comparison with Howe's Approximation for Capacitance of a Rectangle

Howe[8] has shown that the capacitance of a plane conductor is well approximated by a value Q/P_{avg}, where the charge Q is assumed as uniformly distributed over the conductor and P_{avg} is the average value of the resulting potential distribution over the body. Proceeding thus, he found for a rectangle of height $2h$ and width $2w$ that

$$C=2(wh)^{1/2}/2\alpha^{1/2}[(\sinh^{-1}\alpha)/\alpha+\sinh^{-1}(1/\alpha)+\alpha/3+1/3\alpha^2-(\alpha^2+1)^{3/2}/3\alpha^2]$$
$$=2K(wh)^{1/2} \tag{8}$$

where $\alpha=w/h$ and corresponding values of α and K are as shown in Table III.

For the capacitance of a square, Howe's equation yields $C\cong 0.374$ μμf. The nearly exact value, as comprised in Fig. 4 and Table II, is 0.402 μμf. Thus Howe's value for the square is low. On the other hand, for the capacitance of a 3 by 1 rectangle, Howe's equation yields $C=2K(w/h)^{1/2}=3(0.36)=0.623$ esu $=0.692$ μμf, which value is in good agreement with the subarea value of $C=0.643$ esu $=0.714$ μμf. Here, the error in Howe's value is approximately one-half the error for the case of the square. Again, for the capacitance of a 20 by 1 cm rectangle, Howe's equation yields $C=20(0.532)=2.37$ esu $=2.64$ μμf which value is in excellent agreement with the value of 2.40 esu $=2.66$ μμf, to be extrapolated from the curve calculated by subareas and by comparison with the boundary curves of Fig. 6. Thus, it is to be inferred that for $\alpha\geqslant 3$, Howe's values are in substantial agreement with the exact values of the capacitance of a rectangle.

Accordingly, on the basis of this discussion, it follows that the curve of Fig. 7, plotted with the values of Table IV, yields an excellent approximation to the exact value of the capacitance of a rectangle of any ratio of w/h.

Summary

1. The basic theory of approximate calculation, by the use of subareas, of the capacitance of a rectangular plane area, and of the distribution of charge density over it, is concisely outlined.

2. Illustratively, the method of subareas is employed to obtain an accurate value for the capacitance of a 3 by 1 rectangle.

3. Comparison of Figs. 3 and 4 indicates that the final value of Fig. 3 may be inferred as very close to the corresponding exact value.

4. The normalized curve of Fig. 7 yields the approximate capacitance of a rectangle of any specified ratio w/h of width to length.

Appendix I

Assume that the rectangle of Fig. 8 has a uniform surface charge density of value q. The total charge on an incremental area $dxdy$ is $qdxdy$. Each increment of charge $qdxdy$ contributes to the potential at the center 0 an increment of potential $dV=qdxdy/r$. Accordingly, the total potential at point 0 is

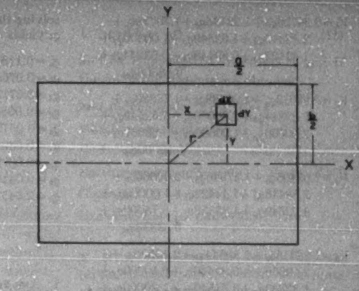

Fig. 8. Co-ordinate system for calculation of potential at center of uniformly charged rectangular subarea

$$V=4q\int_{y=0}^{\frac{b}{2}}\int_{x=0}^{\frac{a}{2}}\frac{dydx}{r}=4q\int_0^{\frac{b}{2}}\int_0^{\frac{a}{2}}\times\frac{dydx}{(x^2+y^2)^{1/2}}$$
$$=4q\left\{\frac{b}{2}\ln\left[\frac{a/2}{b/2}+\left(\frac{(a/2)^2}{(b/2)^2}+1\right)^{1/2}\right]+\frac{a}{2}\ln\left[\frac{b/2}{a/2}+\left(\frac{(b/2)^2}{(a/2)^2}+1\right)^{1/2}\right]\right\} \tag{9}$$

For the case of a 3 by 1 rectangle, plotted as the first approximation of Fig. 3,

$$V=4q\left\{\frac{1}{2}\ln\left[\frac{1.5}{0.5}+(3^2+1)^{1/2}\right]+\frac{3}{2}\ln\left[\frac{1}{3}+\left(\frac{1}{3^2}+1\right)^{1/2}\right]\right\}$$
$$=4q\{1.399\}=5.596q \tag{10}$$

Hence

$$C=Q_t/V=3q/5.596q=0.536\text{ esu}=0.597\ \mu\mu f \tag{11}$$

Appendix II

The set of equations for the charge densities, assumed uniform, of the subareas of Fig. 2 are

$$V_a=4.27175q_a+1.72741q_b+1.17833q_c+0.099636q_d+0.47360q_e+0.24253q_f+0.51233q_g+0.61159q_h+0.84853q_k+1.12403q_m$$

$$V_b=1.72741q_a+4.35027q_b+1.83289q_c+1.32715q_d+0.61067q_e+0.31622q_f+0.68973q_g+0.90322q_h+1.16439q_k+0.84853q_m$$

$$V_c=1.17833q_a+1.83289q_b+4.49909q_c+2.05787q_d+0.85355q_e+0.44720q_f+1.02333q_g+1.24253q_h+0.90322q_k+0.61159q_m$$

$$V_d=0.99636q_a+1.32715q_b+2.05787q_c+4.87904q_d+1.44720q_e+0.70711q_f+1.44720q_g+1.02333q_h+0.68973q_k+0.51233q_m$$

$$V_e=0.94720q_a+1.22135q_b+1.70710q_c+2.89440q_d+4.02549q_e+1.00000q_f+1.41422q_g+0.89440q_h+0.63244q_k+0.48506q_m$$

$$V_f=0.97012q_a+1.26488q_b+1.78880q_c+2.82844q_d+2.00000q_e+3.52549q_f+2.00000q_g+1.00000q_h+0.66667q_k+0.50000q_m$$

$$V_g=1.02466q_a+1.37946q_b+2.04666q_c+2.89440q_d+1.41422q_e+1.00000q_f+4.02549q_g+1.33333q_h+0.75000q_k+0.53333q_m$$

$$V_h=1.22318q_a+1.80644q_b+2.48506q_c+2.04666q_d+0.89440q_e+0.50000q_f+1.33333q_g+3.77549q_h+1.20000q_k+0.66667q_m$$

$$V_k=1.69706q_a+2.32878q_b+1.80644q_c+1.37946q_d+0.63244q_e+0.33333q_f+0.75000q_g+1.20000q_h+3.69216q_k+1.14285q_m$$

$$V_m=2.24806q_a+1.69706q_b+1.22318q_c+1.02466q_d+0.48506q_e+0.25000q_f+0.53333q_g+0.66667q_h+1.14285q_k+3.65049q_m \quad (12)$$

Imposing the condition $V_0=V_a=V_b=V_c=V_d=V_e=V_f=V_g=V_h=V_k=V_m$ and solving the resulting set of equations for the q_i yields

$$\begin{aligned} q_a&=0.11549V_0\\ q_b&=0.07698V_0\\ q_c&=0.07121V_0\\ q_d&=0.06862V_0\\ q_e&=0.06790V_0\\ q_f&=0.03945V_0\\ q_g&=0.03992V_0\\ q_h&=0.04169V_0\\ q_k&=0.04574V_0\\ q_m&=0.08441V_0 \end{aligned} \quad (13)$$

Discussion

James D. Horgan (Marquette University, Milwaukee, Wisc.): In connection with boundary value problems, it is interesting to note that, in recent years, emphasis in analysis and research has shifted from problems involving Laplace's equation to problems involving the wave equation. Countless papers have appeared recently which analyze diffraction effects due to conductors of simple geometry. Yet there are still many unsolved problems which require the solution of Laplace's equation, subject to mixed boundary conditions. Although the equation itself is simpler, the boundary conditions in these problems make them extremely difficult to solve. The problem solved in this paper is typical of these.

The writer has had occasion recently to seek out and compare various means of solving Laplacian field problems with mixed boundaries, and has found that in many instances the method of subareas is the best, indeed, the only practical means, of solution. The recent paper by Higgins and Black,[1] in which the question of the capacitance of strip transmission lines was resolved and previous results shown to be in error, illustrates this fact. With the increased use of electronic computing facilities, this method will find ever-widening application by researchers in the field.

Daniel K. Reitan and **Thomas J. Higgins:** The authors appreciate Prof. Horgan's favorable comment, and agree with him that often the subarea method offers the best practical means of solution of a boundary value problem characterized by Laplace's equation.

In addition to Prof. Horgan's note of his reference 1, the authors would direct attention to the pertinent complementary reference 1, wherein the results obtained analytically in the paper are substantiated by those obtained by electrolytic tank measurements, and to reference 2, which encompasses an account of the whole of Dukes' investigations.

Finally, Prof. Horgan's remarks as to the utility of the subarea approach in conjunction with high-speed computers are well substantiated by the interesting studies effected in precisely this manner by Gross:[3,4] who conjoined knowledge of the subarea method and a high-speed digital calculator to obtain accurate determinations of charge distribution over grounding plates for high-voltage systems.

Electrical Units and Dimensions

LEO YOUNG
MEMBER AIEE

Synopsis: A method is developed for converting between the units and the equations in different systems of units. The appearance or nonappearance of 4π as a constant of proportionality in Maxwell's equations may be attributed to switching the unit of solid angle between sphere and steradian. Treatment of angle as a dimension leads to a convenient and systematic way of conversion between different systems.

In electrical engineering the meter-kilogram-second (mks) rationalized system of units is generally adopted. Sometimes, however, the engineer encounters another system, such as one of the centimeter-gram-second systems commonly used in physics. He may work out the formula and convert his final answer from tables. Frequently he prefers to derive the formula over again by using mks rationalized units and equations throughout. In this paper, a method and a nomenclature will be developed to include the six systems of electrical units in general use. By explicitly introducing angle and solid angle, which are at the root of the diversity of constants, it becomes possible to write Maxwell's equations in a "universal" notation. By appealing to angle and solid angle constants as dimensional quantities, it becomes possible to introduce them into any equation in a given system as the missing dimensions. When the numerical values of the angle constants in the various systems of units are known, the equation can then be converted into any desired system.

A physical quantity, in addition to its four dimensions of fource F, length L, time T, and charge Q, becomes associated with two "angle" dimensions, plane angle U and solid angle S. (Force rather than mass is chosen only for convenience in dimensional computations. Charge is chosen for the electrical dimension to avoid fractional indexes.) To compare units of different systems, write down the six dimensions of the unit, and take the ratio with the respective units of F, L, T, Q, S, and U substituted.

It is not proposed to discuss the philosophical or the operational aspect of angle dimensions. In presenting this method it is only claimed that: (1) it is self-consistent, (2) it gives a simple procedure for converting between different systems, and (3) angle dimensions are justified if only because they provide a nomenclature easy to remember and to apply.

Angle Dimensions

In the mks rationalized system

$$\operatorname{div} \mathbf{D} = \rho \tag{1}$$

In the mks unrationalized system

$$\operatorname{div} \mathbf{D} = 4\pi\rho \tag{2}$$

Applying this to a point charge Q, and taking the flux over a spherical surface with the charge at its center,

$$\text{flux of } \mathbf{D} \text{ over the sphere} = Q \tag{3}$$

in rationalized mks units, and

$$\text{flux of } \mathbf{D} \text{ over the sphere} = 4\pi Q \tag{4}$$

in unrationalized mks units. Equation 4 can also be written

$$\text{flux of } \mathbf{D} \text{ per steradian} = Q \tag{5}$$

while equation 3 could equally well be written

$$\text{flux of } \mathbf{D} \text{ per sphere} = Q \tag{6}$$

Equations 5 and 6 are the same except for the units of solid angle. Equations 1 and 2 can be combined into the form

$$S^{-1} \operatorname{div} \mathbf{D} = \rho \tag{7}$$

where $S=1$ in mks rationalized units, and $S=4\pi$ in mks unrationalized units. Equations 5 and 6 show that the units of solid angle in the two systems are the sphere and the steradian respectively, and that the dimensions of $\mathbf{D}$ are $[L^{-2}QS]$.

As "div" is the limit of flux over a small closed surface, so "curl" is the limit of "rotation" round a small loop. The reciprocal angle constant U^{-1} is thus associated with curl as S^{-1} is associated with div.

Maxwell's equations can now be written

$$\operatorname{div} \mathbf{D} = S\rho \tag{8}$$

$$\operatorname{div} \mathbf{B} = 0 \tag{9}$$

$$U^{-1} \operatorname{curl} \mathbf{H} = S\mathbf{j} + \dot{\mathbf{D}} \tag{10}$$

$$U^{-1} \operatorname{curl} \mathbf{E} = -\dot{\mathbf{B}} \tag{11}$$

and by choosing the constants S and U the following systems are obtained.

mks rationalized: $S=1$, $U=1$
mks unrationalized: $S=4\pi$, $U=1$
electrostatic units (esu): $S=4\pi$, $U=1$
electromagnetic units (emu): $S=4\pi$, $U=1$
Gaussian: $S=4\pi$, $U=1/\gamma$
Heaviside-Lorentz units (hlu): $S=1$, $U=1/\gamma$

γ is a dimensionless number equal (approximately) to 3×10^{10}. The units of angle in each system are

mks rationalized: sphere, turn
mks unrationalized: steradian, turn
esu: steradian, turn
emu: steradian, turn
Gaussian: steradian, γ turns
hlu: sphere, γ turns

Application of Angle Dimensions

The application of angle dimensions can best be seen from two simple examples. First, let it be required to find the ratio of the mks rationalized unit of magnetic field to the mks unrationalized unit. Taking charge Q as the electrical dimension, the full dimensions (see Table I) of magnetic field are $[L^{-1}T^{-1}QSU]$. The required ratio is therefore as sphere is to steradian (since all the other units are the same), which is 4π.

Second, let it be given that the energy density of the electrostatic field in esu is $\mathbf{ED}/8\pi$. It is required to find the expression in mks rationalized units. The missing dimension is assumed to be S^x

$$[E][D][S^x] = [\text{energy}][L^{-3}]$$

and balancing dimensions (see Table I), $x=-1$. Now $S=4\pi$ in esu. Therefore, the expression in all systems of units is $(\mathbf{ED}/8\pi)\times(4\pi/S)$, which is $S^{-1}\mathbf{ED}/2$. In the mks rationalized system $S=1$, and so this reduces to $\mathbf{ED}/2$.

From Maxwell's equations 8, 9, 10, 11, and one force equation such as

$$\mathbf{E}Q = \mathbf{F} \tag{12}$$

the dimensions of any quantity can be found.

With charge Q as the electrical dimension, it is necessary to know that

$$\begin{aligned} 1 \text{ coulomb} &= \frac{1}{10} \text{ emu of charge} \\ &= 3\times 10^{9} \text{ esu (approximately)} \\ &= 3\times 10^{9} \text{ Gaussian units} \\ &= 3\sqrt{4\pi}\times 10^{9} \text{ hlu} \end{aligned}$$

in order to find the ratio of unit quantities in different systems of units. (Also, 1 newton $= 10^5$ dynes.)

Paper 56-984, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 1–5, 1956. Manuscript submitted April 2, 1956; made available for printing August 3, 1956.

Leo Young is with the Westinghouse Electric Corporation, Baltimore, Md.

To prove the relation between the hlu of charge and the esu of charge,

$$[\epsilon_0]=[F^{-1}L^{-2}Q^2S]$$

therefore

$$[Q]=[\epsilon_0^{1/2}F^{1/2}LS^{-1/2}] \tag{13}$$

The hlu and the esu of E_0, F, L are the same. Therefore

$$\frac{1\text{ esu of charge}}{1\text{ hlu of charge}}=\left(\frac{1\text{ hlu of solid angle}}{1\text{ esu of solid angle}}\right)^{1/2}$$

$$=\left(\frac{1\text{ sphere}}{1\text{ steradian}}\right)^{1/2}$$

$$=\sqrt{4\pi}$$

Table I gives the dimensions of some common quantities. A list of some typical dimensionally complete equations is given in the Appendix.

Summary

It has been shown that insertion of a constant S into the equations describing electromagnetic phenomena makes it possible to unite the equations of four systems (both mks systems, esu, and emu) into a single form. *Since S is a constant of proportionality in the defining equations,* it may be treated as a fifth dimension and introduced wherever it is missing in an equation by balancing dimensions. Moreover, it was shown how S takes the numerical value 1 or 4π according to the unit of solid angle chosen.

It was found convenient and natural to identify the dimensional constant S with solid angle. Combining the two then produces "dimensions in solid angle." This gives not only a method, but also a nomenclature based on the nature of the problem.

Similarly, introducing (plane) angle dimension U allows the two remaining systems of units, Gaussian and hlu, to be included.

Table I. Dimensions and Name in mks Rationalized Units of Some Common Quantities

Quantity	Symbol	Dimensions F	L	T	Q	S	U	Name in mks Rationalized Units
Charge	Q				1			coulomb
Electric field intensity	$\mathbf{E}$	1			−1			volt per meter
Electric displacement	$\mathbf{D}$		−2		1	1		coulomb sphere per meter²
Permittivity	ϵ_0	−1	−2		2	1		farad sphere per meter
Polarization	$\mathbf{P}$		−2		1			coulomb per meter²
Current	I			−1	1			ampere
Magnetic field intensity	$\mathbf{H}$		−1	−1	1	1	1	ampere-turn sphere per meter
Magnetic induction	$\mathbf{B}$	1	−1	1	−1		−1	weber per meter²
Wave impedance	Z_w	1	1	1	−2	−1	−1	ohm per turn sphere
Permeability	μ_0	1		2	−2	−1	−2	henry per meter sphere turn²
Magnetic flux	Φ	1	1	1	−1		−1	weber
Pole strength (defined by $p\mathbf{H}=\mathbf{F}$)	p	1	1	1	−1	−1	−1	weber per sphere
Intensity of magnetization	J	1	−1	1	−1	−1	−1	weber per sphere meter²
Electric potential, emf	V	1	1		−1			volt
Resistance	R	1	1	1	−2			ohm
Capacitance	C	−1	−1		2			farad
Inductance	$\mathcal{L}$	1	1	2	−2			henry
Conductivity	σ	−1	−2	−1	2			mho per meter
Resistivity	r	1	2	1	−2			ohm meter
Magnetomotive force, mmf	h			−1	1	1	1	ampere-turn sphere
Reluctance	$\mathcal{R}$	−1	−1	−2	2	1	2	ampere-turn sphere per weber

Note especially the difference in dimensions between such quantities as **D** and **P**, I and h, **B** and J, R and Z_w, Φ and p.

Appendix

Some typical dimensionally complete equations are as follows:

Force between two charges Q_1 and Q_2 in free space and distance d apart,

$$F=\frac{S}{4\pi}\frac{Q_1Q_2}{\epsilon_0 d^2} \tag{14}$$

Force on current element $Id\mathbf{s}$ in magnetic induction field **B**,

$$d\mathbf{F}=UId\mathbf{s}\times\mathbf{B} \tag{15}$$

Force per unit length between two infinite straight wires carrying currents I_1 and I_2 in free space and distance d apart,

$$F=\frac{U^2S}{2\pi}\mu_0\frac{I_1I_2}{d} \tag{16}$$

Energy density of electromagnetic field

$$=\frac{1}{2}S^{-1}(\mathbf{ED}+\mathbf{HB}) \tag{17}$$

Electric displacement in a medium subject to an electric field **E**, which produces a polarization **P**,

$$\mathbf{D}=\epsilon_0\mathbf{E}+S\mathbf{P} \tag{18}$$

Capacitance of parallel plate capacitor of area A, plate separation t, assuming parallel lines of force,

$$C=\frac{\epsilon_0}{S}\frac{A}{t} \tag{19}$$

Self-inductance of long solenoid of cross-section A, length b, and a total of N turns,

$$\mathcal{L}=U^2S\mu_0N^2A/b \tag{20}$$

Magnetic moment $d\mathbf{M}$ of current I flowing round an area $d\mathbf{A}$,

$$d\mathbf{M}=U\mu_0Id\mathbf{A} \tag{21}$$

Discussion

F. T. Chapman (Bexleyheath, Kent, England): In this paper Mr. Young has shown the advantage of including dimensions for plane and solid angles in some of the dimensional equations used in electrical theory. Plane and solid angles are physical quantities but so long as they are defined as ratios, namely, arc per radius and area per (radius)² respectively, they are dimensionless; that is, there are no dimensional quantities the size of whose units can affect the size of the units of angle. But there are other methods of measuring plane angle in arbitrary units such as degrees, quadrants, or revolutions (turns), and, in the case of solid angle, there is the alternative of the sphere. The balance of equations will be affected and the measure numbers of quantities which are defined in terms including angular measurement will be changed by a change from one unit of angle to another. This consideration justifies the inclusion of a measure number for angle in equations 7–11, for example, and the inclusion of a dimension for angle in such dimensional expressions as Mr. Young gives for Q in equation 13.

Carl C. Chambers (University of Pennsylvania, Philadelphia, Pa.): This paper is a very material contribution to the field. In particular, it shows clearly that the 4π's that appear or do not appear in the various systems of units are identified with the concept of an angle. When the angle is defined as the ratio of two lengths without the specification of a constant, the logical unit of angle is steradian. Otherwise the units are said to lack coherency. Of course, in many systems of units the angle is defined as a proportion of a circle, or in the case of a solid angle as a proportion of a sphere. Under these conditions the terms, angle and solid angle, are related to the fundamental quantities of length in a quite different manner than in the case of their definitions which lead coherently to radians and steradians. In spite of its value in emphasizing the dependence of the presence or absence of 4π on the concept of angle, this paper in common with many other papers on this subject falls short of clarifying the confusing concepts of physical quantities, units, and dimensions. "Physical quantities" are measurable physical concepts. "Units" are samples of those measurable quantities. "Dimensions" are those characteristics of physical quantities which are specified by the algebraic powers of the chosen fundamental quantities which enter into the specification of the given physical quantities. Thus velocity has the dimensions, distance to the first power over time to the first power, and this is irrespective of the units of velocity or length or time. I am confident that Mr. Young did not mean this particular concept when he suggested that the S and the U in his paper be added dimensions. I might suggest that he substitute the words physical quantity and the meaning for his use of the word dimension in this respect. However, this would explicitly move into the middle of the real controversy which is going on in international circles concerning the meaning of rationalization. This controversy rests squarely with the interpretation of the definitions, first of physical quantity and second of unit. Some scientists considering the definition that physical quantities are those measurable concepts concerning an experimental setup, insist that this means that it is not a physical quantity until the definition in terms of the selected fundamental physical quantities is such that the reader of the definition knows explicitly how to measure that quantity.

I have suggested that this particular term should be "specific physical quantity." This would be in contrast to what might be called "generalized physical quantity" which would then mean a physical concept which was defined by a law of physics with a constant of proportionality yet to be determined. Thus in the paper, equation 3 which related the flux of **D** over a sphere as equal to Q would define **D** as a different specific physical quantity from his equation 4 which defines **D** by the statement flux of **D** over a sphere equal $4\pi Q$. According to my suggested definitions of two different physical quantities, the **D**'s in equations 3 and 4 would be different specific physical quantities while being the same generalized physical quantity. The difference between these two **D**'s as specific physical quantities is expressed explicitly in a different way in his equations 5 and 6.

This paper pedagogically presents a method which will help to show how the 4π's that appear or do not appear may be related back to their fundamental source, the concept of an angle. However, they do not contribute to the extent of solving the international contentions which are current with regard to the meaning of rationalization and its relationship to physical quantities on the one hand and to units on the other.

R. O. Kapp (Kennedy and Donkin, London, England): Mr. Young's proposal to raise angle to dimensional status is to be welcomed, for there are many occasions when it serves a useful purpose in dimensional equations. Science has suffered considerably in the past from the erroneous tradition that only three quantities, mass, length, and time, should be used. That tradition is not yet quite dead.

If I have any criticism of Mr. Young's method of relating rationalization to theory of dimensions, it is only that I could wish him to have gone further and made a more sweeping generalization. I have shown in a paper scheduled to be read before the Institution of Electrical Engineers (British) that the difference between rationalized and unrationalized expressions can be clarified if one gives dimensional status to a configuration measure. Any symmetrical area could then be expressed as σd^2, where d is the distance across the area. By a sound tradition this is equated to $\pi/4$ for a circle. If this convention is applied consistently, a system of units based on the 1-to-1 ratio is rationalized. If, however, the configuration factor is so chosen that its value is 1/16 for a circle, a system of units built on the 1-to-1 ratio is unrationalized. Table II, taken from my paper, makes this clear.

Table II. Alternative Systems of Units

Take as Basis the Definition of Field Strength $E=\psi/a\epsilon$, Where ψ/a Is the Flux Density

	Value		
	Conventional		Unconventional
Quantity	Coherent Rationalized	Uncoherent Unrationalized	Coherent Unrationalized
Relation between flux and charge	$\psi=Q$	$\psi=4\pi Q$*	$\psi=Q$
Area of circle	πr^2	πr^2	$r^2/4$†
Area of sphere	$4\pi r^2$	$4\pi r^2$	r^2†
Field strength E round a point charge	$Q/4\pi r^2\epsilon$	$Q/r^2\epsilon$	$Q/r^2\epsilon$

*Uncoherent.

†Unconventional.

An unrationalized system requires that one sacrifice either coherence or convention. In other words, an unrationalized system can only be coherent if expressions for areas are unrationalized.

J. J. Smith (General Electric Company, Schenectady, N. Y.): Mr. Young presents an interesting approach to the relations between the units in different electric systems by introducing the two units of solid angle, the sphere and the steradian. In the centimeter-gram-second (cgs) unrationalized system the unit used for a solid angle was the steradian. The mks unrationalized system can be similarly derived, using the steradian as a unit for the solid angle.

In the derivation of the rationalized mks system from current as the fourth fundamental unit no use is usually made of solid angles. It is based on the following definition of the ampere as given in the revision of ASA *C42* "Standard Definitions of Electrical Terms": "The ampere is a unit of current of such magnitude that if 1 ampere is maintained constant in each of two straight parallel conductors of infinite length and of negligible circular sections placed 1 meter apart in a vacuum, a force will be produced equal to 2×10^{-7} newtons per meter of length."

However, it is found that if solid angles are used, the sphere must be used as a unit in the rationalized system. Thus it might be expected that some of the formulas in a rationalized system will differ from those in an unrationalized system by some power of 4π which is the ratio of one sphere to one steradian.

His results appear to cover the six systems to which he refers. However, in its present form it has the disadvantage that it requires a change in the names of some of the units in the mksa system which have been worked out by standardizing bodies such as American Standards Association and International Electrotechnical Commission. For instance, in Table I the name of the unit for electric displacement density **D** is given as the "coulomb sphere per square meter" instead of the "coulomb per square meter" generally used.

This change in the name of accepted units may be avoided by giving a slightly different interpretation to the symbols S and U as shown in equation 22. Let us start with equation 3 which may be written

$$\int\int \mathbf{D}_r dA = Q \tag{22}$$

Following Maxwell we shall consider the symbols **D**, A, and Q to denote only numerical values. The subscript r denotes it is the numerical value of **D** in the rationalized system.

Equation 22 may be simplified for this discussion by assuming that Q is at the center of a sphere over which D is uniform. On integrating we get

$$4\pi R^2 D_r = Q \tag{23}$$

where R is the radius of the sphere and the suffix r is used to indicate that D_r is the numerical value in the rationalized system. In the following discussion of this equation we shall consider the cgs system both in the rationalized and unrationalized form. The reason for using the cgs system is that names have been given to the rationalized and unrationalized units in that system, namely the statcoulomb and the line. The unit corresponding to the statcoulomb is the coulomb in the mksa system but no name has been given to the unit which corresponds to the centimeter-gram-second unit "line" in the mksa system. Suggestions have been made that it be called the "pra-line."

We may associate numerical equation 23 with its appropriate unit by adding the unit statcoulomb to each side of the equation

$$4\pi R^2 D_r \text{ statcoulombs} = Q \text{ statcoulomb} \tag{24}$$

This gives

$$D_r \text{ statcoulombs per square centimeter} = \frac{Q}{4\pi R^2} \text{ statcoulombs per square centimeter} \tag{25}$$

The numerical equation corresponding to equation 23 in the unrationalized system is

$$R^2 D_u = Q \tag{26}$$

where D_u denotes the numerical value in the cgs unrationalized system. Since the unit in that system is the line we have

$$D_u \text{ lines per square centimeter} = \frac{Q}{R^2} \text{ lines per square centimeter} \tag{27}$$

In the unrationalized cgs system it was held that unit charge gave rise to 4π lines where the statcoulomb was the unit in the rationalized system and the line was the unit in the unrationalized system. Thus

$$1 \text{ statcoulomb} = 4\pi \text{ lines} \tag{28}$$

and

$$1 \text{ statcoulomb per square centimeter} = 4\pi \text{ lines per square centimeter} \tag{29}$$

But

$$\begin{aligned} 1\ \frac{\text{statcoulomb}}{\text{square centimeter}} &= 1\ \frac{\text{statcoulomb}}{\text{square centimeter}}\ \frac{4\pi \text{ steradians}}{\text{sphere}} \\ &= 4\pi\ \frac{\text{statcoulomb}}{\text{square centimeter}}\ \frac{\text{steradians}}{\text{sphere}} \end{aligned} \tag{30}$$

Thus, comparing this with equation 29 we may write

$$1\ \frac{\text{statcoulomb}}{\text{square centimeter}}\ \frac{\text{steradian}}{\text{sphere}} = 1 \text{ line per square centimeter} \tag{31}$$

Hence we obtain the unit of electric displacement density in the unrationalized system from the unit in the same rationalized system by multiplying it by the ratio of the steradian to the sphere.

This ratio of the steradian to the sphere is the same as Young's S^{-1} so we may write

$$S_u^{-1} = \frac{1 \text{ steradian}}{1 \text{ sphere}} = \frac{1}{4\pi} \tag{32}$$

where the subscript u denotes it is the value used in the case of an unrationalized system. Similarly we may write

$$S_r^{-1} = \frac{1 \text{ sphere}}{1 \text{ sphere}} = 1 \tag{33}$$

where the symbol r denotes it is the value used in the case of a rationalized system.

In the same way it can be shown in the case of magnetic field strength H that the rationalized unit, the ampere-turn per meter, is related to the unrationalized unit, the millioersted, by the equation,

$$1\ \frac{\text{ampere-turn}}{\text{meter}}\ \frac{\text{steradian}}{\text{sphere}} = 1 \text{ millioersted} \tag{34}$$

or

$$1 \text{ ampere-turn per meter} = S_u \text{ millioersteds} = 4\pi \text{ millioersteds} \tag{35}$$

The reason for the introduction of the factor 3×10^{10} in the Gaussian and Heaviside-Lorentz systems was that the electrical quantities were measured in the esu system and the magnetic quantities were measured in the emu system. See for instance Jeans "Electricity and Magnetism."[1] To convert the numerical value of the voltage in esu system to its numerical value in the emu system the following equation was used

$$1 \text{ stat volt} = 3 \times 10^{10} \text{ abvolts} \tag{36}$$

Thus, starting with the mks system equation 11 in the paper,

$$\text{curl } \mathbf{E} = -\dot{\mathbf{B}} \tag{37}$$

Integrating this around a complete circuit gives

$$e = \oint \mathbf{E}.ds = -\dot{\phi} \tag{38}$$

adding the units to this it becomes in the mks system

$$e \text{ volts} = -\dot{\phi} \text{ volts} \tag{39}$$

In the cgs emu system it is

$$e \text{ abvolts} = -\dot{\phi} \text{ abvolts} \tag{40}$$

and in the cgs esu system it is

$$e \text{ statvolts} = -\dot{\phi} \text{ statvolts} \tag{41}$$

The Gaussian and Heaviside-Lorentz systems used the equation in a form where e was the numerical value of the voltage in the esu system, and $\dot{\phi}$ was the numerical value of the voltage in the emu system. Thus inserting the units in this manner

$$\begin{aligned} e_s \text{ statvolts} &= -\dot{\phi}_m \text{ abvolts} \\ &= -\dot{\phi}_m \text{ statvolts} \times \frac{1 \text{ abvolts}}{1 \text{ statvolt}} \\ &= -\frac{1}{3 \times 10^{10}}\, \dot{\phi}_m \text{ statvolts} \end{aligned} \tag{42}$$

where the subscript s denotes it is the numerical value in the esu system and the subscript m denotes the numerical value in the emu system. Since the units are the same on both sides they may be omitted and the numerical equation written in the usual form. The subscripts s and m are usually omitted at the same time

$$e = -\frac{1}{3 \times 10^{10}}\, \dot{\phi} \tag{43}$$

We can now identify Young's U as follows. In a mixed system where the numerical values are given in statvolts on one side of the equation, and are given in abvolts on the other side (mixed system)

$$U_m^{-1} = \frac{1 \text{ statvolt}}{1 \text{ abvolt}} = 3 \times 10^{10} \tag{44}$$

The corresponding value when the numerical values are given in the same units on both sides of the equation is (nonmixed system)

$$U_n^{-1} = \frac{1 \text{ statvolt}}{1 \text{ statvolt}} = \frac{1 \text{ abvolt}}{1 \text{ abvolt}} = 1 \tag{45}$$

It may be helpful to write Young's equations 8 and 10 with the appropriate units on each side using the cgs system since names for all the units are available

$$\begin{aligned} \text{div } \mathbf{D}_r \text{ statcoulombs per cubic centimeter} &= \rho \text{ statcoulombs per cubic centimeter} \\ \text{div } \mathbf{D}_u \text{ lines per cubic centimeter} &= 4\pi\rho \text{ lines per cubic centimeter} \\ \text{curl } \mathbf{H}_r\ ab\ At \text{ per square centimeter} &= (i_m + \dot{D}_m)ab\ At \text{ per square centimeter} \\ &= \frac{1}{3 \times 10^{10}}(i_s + \dot{D}_s)\ ab\ At \text{ per square centimeter} \\ \text{curl } \mathbf{H}_u \text{ gilberts per square centimeter} &= 4\pi(i_m + \dot{D}_m) \text{ gilberts per square centimeter} \\ &= \frac{4\pi}{3 \times 10^{10}}(i_s + \dot{D}_s) \text{ gilberts per square centimeter} \end{aligned} \tag{46}$$

Here the subscripts r, u, m, and s are used for the sake of clarity. It should be recognized that when the units are dropped from each side of the equation to obtain numerical equations, the subscripts are also usually dropped, giving the following set of numerical equations for curl **H**

$$\begin{aligned} \text{curl } \mathbf{H} &= i + \dot{\mathbf{D}} \\ \text{curl } \mathbf{H} &= \frac{1}{c}(i + \dot{\mathbf{D}}) \\ \text{curl } \mathbf{H} &= 4\pi(i + \dot{\mathbf{D}}) \\ \text{curl } \mathbf{H} &= \frac{4\pi}{c}(i + \dot{\mathbf{D}}) \end{aligned} \tag{47}$$

Each of these numerical equations belongs to a different system. The system to which each belongs is readily found from equation 10, or from equation 46, if only the cgs system is considered.

By interpreting Young's S and U in the manner shown here, the change in the names of the mks units given in Table I is avoided. This seems quite desirable since these names have been worked out in the American Standard Association and International Electrochemical Commission and are used extensively by many authors.

REFERENCE

1. ELECTRICITY AND MAGNETISM (book), J. H. Jeans. Cambridge University Press, London, England, second edition, 1911, p. 500.

Leo Young: It is a pleasure to note in the discussions so much fundamental agreement with the method described. This approach has evidently been shared by others who have concerned themselves with the subject.

Dr. Chapman points out that the balance of equations is affected and the measure numbers of quantities change, which are both the result of changing units of angle. So long as angle is defined as a ratio, with always a fixed constant of proportionality, it remains dimensionless and no way exists to handle a situation where a change of angle units occurs.

Dr. Chambers distinguishes between physical quantities, units, and dimensions. In trying to be brief, and wishing to emphasize the main argument, I did not refer to them. To take Dr. Chambers' example, velocity is defined as length divided by time. Let us introduce a constant of proportionality, k, and write

$$\text{velocity} = k \times \frac{\text{length}}{\text{time}} \tag{48}$$

Then the constant k would appear wherever a physical quantity is defined directly in terms of velocity, rather than in terms of length and time separately.

Every physical quantity has to be defined by one of two alternative methods: (1) in terms of an arbitrary unit by direct comparison, or (2) in terms of other quantities by some arbitrary process. If the former, it is referred to as a fundamental (or primary) quantity; if the latter, as a derived (or secondary) quantity. For a derived quantity the definition takes the form of an equation such as equation 48, and involves an arbitrary constant of proportionality. It is largely a matter of choice whether we decide to take a given physical quantity as fundamental or derived. However, there is a minimum number of fundamental quantities less than which we cannot have. In mechanics there are three, in electromagnetism there is also a fourth fundamental quantity.

The unit of a derived quantity changes whenever we change the units of the fundamental quantities on which it depends through its defining equation, or whenever we change the constant of proportionality in that equation.

The equations do not change with the fundamental units, but only with the constants or proportionality.

With any electrical quantity there are associated four primary dimensions which may be taken to be force F, length L, time T, and charge Q. These dimensions are assigned to a quantity through its defining equation. The process may be summarized as follows. Strip the defining equation of its constant of proportionality and all operator symbols (such as differential or integral operators), leaving only the symbols F, L, T, and Q. If necessary, first reduce all previously defined derived quantities to their primary dimensions in F, L, T, and Q. This turns the defining equation into the dimensional formula of the quantity defined. It tells how the unit of the derived quantity changes when the units of the fundamental quantities are changed.

In the process of obtaining the dimensional formula, the information carried by the constant of proportionality in the defining equation has been lost. For most equations and in most systems this constant is unity, and the information is of no consequence. Sometimes, however, this information is worth preserving.

Consider for instance equation 1 which defines D. When div is replaced by its dimensional value, and S is dropped, it gives the dimensional formula of D,

$$[D]=[L^{-2}Q] \qquad (49)$$

Suppose however S is left in, so that

$$[D]=[L^{-2}QS] \qquad (50)$$

where $[S]$ is kept as a fifth dimension. We speak of $[S]$ as a secondary dimension, to distinguish it from the minimum number of (four) primary dimensions. Its usefulness lies in the possibility of treating a change of equations as a change of units, since the generalized equations remain the same.

The constant k in equation 48 could be left in the dimensional formula for velocity, and would be referred to as a secondary dimension of velocity in the sense just explained. However, k, S, and U do not possess primary dimensions in the sense of F (or M), L, T, and Q.

I think the foregoing statement is akin to the contribution from Professor Kapp, who makes a similar point.

Dr. Smith gives an interesting derivation of certain relations between units of different systems, using the two values of the constant S: $S_u=4\pi$ and $S_r=1$. He goes on to show how the two values of U, $U_m \doteqdot 1/(3\times10^{10})$ and $U_u=1$, are the result of mixing or not mixing esu with emu (U_m is the same as $1/\gamma$. Dr. Smith's c in equation 47 is my γ. I wished to avoid using c for U_m which is a dimensionless number $\gamma \doteqdot 3\times10^{10}$, while c is usually taken for the velocity of light, which has this particular numerical value only when it is measured in centimeters per second. Thus in my notation c is not γ, but $c=\gamma$ centimeters per second = 186.000 miles per second, etc.).

He thus obtains the same results as using angle dimensions. He has the advantage of being thoroughly familiar with the basic relationships between units, whereas my method is intended for those who are not so familiar, or who prefer a quicker method, which has most of this information already "built into it." Once understood, it requires the minimum of effort when applied to practical problems.

I did not suggest that the names of the "generalized" or "transitional" units in Table I be adopted by the ASA or IEC. They should be thought of as units in transition between two systems. On many occasions this nomenclature would be helpful, particularly when parties using different systems wish to communicate. I also hope that this approach will help engineers and scientists to a better understanding of the subject. How widely it is to be used depends on them.

A New Method for Treating Nonlinear Problems with Applications to Iron-Cored Oscillatory Circuits

I—Subharmonics Do Not Exist

M. KAMAL GOHAR
NONMEMBER AIEE

Synopsis: Nonlinear circuits are now widely used in many control regulation systems or other industrial applications. Most of the solutions of such circuits have been based on either the step-by-step or successive approximation methods which do not always lead to the correct results, except in some special cases. Also, such calculations are complex so that generally the first approximation only is adopted. In this paper a new method for attacking nonlinear problems is suggested. By a certain representation of the nonlinear given relation the amount of work is greatly reduced and the calculations can even be carried out by an ordinary slide rule. According to the author's knowledge, the solution for the case of iron-cored oscillatory circuits and similar cases when the supply frequency, current or voltage, contains considerable harmonics is obtained for the first time. With respect to hysteresis action a simplified solution is given. Experimental results are in good agreement with the theoretical solutions. Harmonics up to the fifth are the only ones used herein to represent the required results. Such representations can be carried out with any number of harmonics by similar process.

PRACTICALLY all single-valued nonlinear relations can be satisfactorily represented by two or three straight lines. Fig. 1 shows the representation of a saturation curve of iron as suggested by Boyajian.[1] In his solution, he used two linear relations, one for each region, and remarked that the transition back and forth between them introduced a transient term into the equation of each region. However, his method led to complicated simultaneous equations which could not be solved except for some special cases. Other authors preferred to express the nonlinear relation in other forms such as Fourier or polynomial series. Figs. 2 and 3 show such a representation by Fourier series for a plate-current–grid-voltage characteristic of a triode and the current-flux relation for an iron-cored coil, respectively.[2,3] Fig. 4 shows another representation for a B-H curve by the use of polynomial series.[4] It took hours to make such representations. Most of the solutions using the foregoing representa-

Paper 56-983, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 1-5, 1956. Manuscript submitted June 10, 1955; made available for printing August 31, 1956.

M. KAMAL GOHAR is with Cairo University, Cairo, Egypt.

The author is indebted to Dr. Abdel Samie Moustafa for his valuable advice, and to Mukhtar Nashid for his permission to use some of his experimental work.

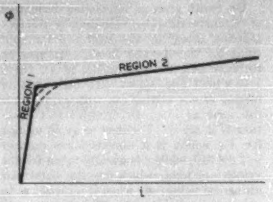

Fig. 1. Representation of saturation curve by two straight lines

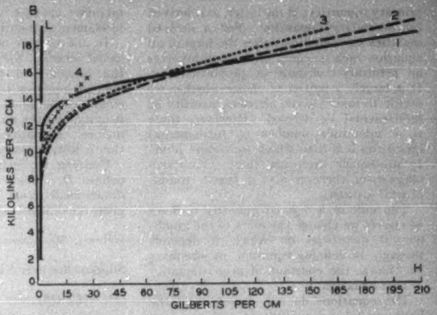
Fig. 4. Representation of B-H curve by polynomial series



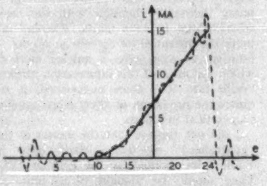


Fig. 2. Representation of i-e curve by Fourier series

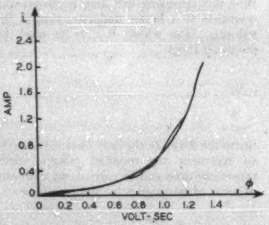

Fig. 3. Representation of i-φ curve by Fourier series

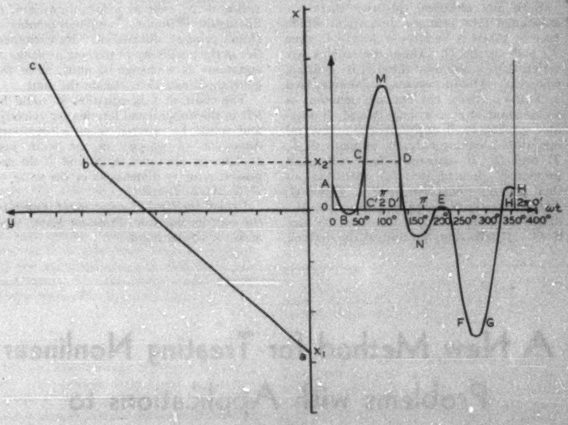

Fig. 5. Oscillatory function under the influence of a nonlinear relation represented by two straight lines

tions were based on either the step-by-step or successive approximation methods which do not always lead to correct results and so they were applied only to some special cases or to small nonlinear systems. In this paper nonlinear relations are represented by certain straight lines in such a way as to avoid successive approximations.

Consider Fig. 5, in which the relation between y and x can be represented by the straight lines ab and bc. Mathematically these lines can be given by

For ab: $y=m_1x_1+C_1,\ x_1<x<x_2$ (1)

For bc: $y=m_2x+C_2,\ x_2<x$ (2)

If x varies periodically with time t and is of the form

$$x=F(\omega t)=A_0+\sum_{n=1} A_n\cos n\omega t+\sum_{n=1} B_n\sin n\omega t \quad (3)$$

represented by the curve $ABCMDNEFGH$, the corresponding expression for y will depend on whether $x_1<x<x_2$ or $x_2<x$. If x is in the first range, $y=m_1x+c_1$, that is,

$$y=m_1[A_0+\Sigma A_n\cos n\omega t+\Sigma B_n\sin n\omega t]+C_1 \quad (4)$$

In general let θ_1 and θ_2 be the values of ωt at which $x=x_2$ represented by the points C and D in Fig. 5 In most practical cases two values of ωt are considered. Dividing $ABCMDNEFGH$ into two parts, $ABCC'D'DEFGH$ can be represented by a Fourier series $F_1(\omega t)$ and therefore $y=m_1F_1(\omega t)+c_1$, and $OC'CMDD'H'$ which can be represented by another Fourier series $F_2(\omega t)$, and hence $y=m_2F_2(\omega t)+C_2$. Therefore, the general expression for y is

$$y=m_1F_1(\omega t)+C_1(\omega t)+m_2F_2(\omega t)+C_2(\omega t) \quad (5)$$

where $C_1(\omega t)$ is a Fourier series to represent a curve of constant value C_1 from $\omega t=0$ to $\omega t=\theta_1$ and from $\omega t=\theta_2$ to $\omega t=2\pi$ while between θ_1 and θ_2 it has a zero value. Similarly, $C_2(\omega t)$ represents a curve of constant value C_2 between $\omega t=\theta_1$ and $\omega t=\theta_2$ and has a zero value for all other values of ωt from $\omega t=0$ to $\omega t=2\pi$.

Sometimes it may be more suitable to write equation 5 in the form:

$$y=m_1F(\omega t)+(m_2-m_1)F_2(\omega t)+(C_2-C_1)\times(\omega t)+C_1 \quad (6)$$

where $(C_2-C_1)(\omega t)$ represents a curve of constant value C_2-C_1 from $\omega t=\theta_1$ to $\omega t=\theta_2$ and has a zero value for all other values of ωt from $\omega t=0$ to $\omega t=2\pi$.

In order to reduce the amount of work, Fourier series for each of $y=A_m\cos m\omega t$, $y=B_m\sin m\omega t$, $y=C_m$ from $\omega t=\theta_1$ to

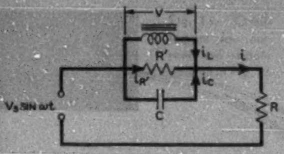

Fig. 6. A nonlinear oscillatory circuit

$\omega t=\theta_2$ with $y=0$ for all other values of ωt from $\omega t=0$ to $\omega t=2\pi$ are given in Appendix I.

The advantage of this method is that after determining the limits of ωt such as θ_1 and θ_2, the theory of superposition can be used. It can be used in two ways with advantage in the solution of differential equations for electric circuits (or otherwise) containing a nonlinear element. Although the first one is longer, not as reliable, and cannot generally be adopted except for small nonlinear cases, it is introduced here as it gives the fundamental idea of the solution.

Theoretical Analysis

A nonlinear differential equation which appears in many applications, the oscillatory circuit shown in Fig. 6, for example, is

$$A\frac{d^2\phi}{dt^2}+B\frac{d\phi}{dt}+i_L=K\sin\omega t \tag{7}$$

The relation between ϕ and i_L is nonlinear and skew. For positive values of ϕ and i_L the relation is shown and represented in Fig. 7. Let ϕ_1 and ϕ_2 be the values of ϕ at the end of the straight-line parts. As a first approximation assuming only the first-line part oa of the $\phi-i_L$ relation, the solution of the differential equation 7 by the ordinary well-known method gives

$$\phi=\phi_m\sin(\omega t+\psi) \tag{8}$$

If $\phi_m>\phi_2$, ϕ can be expressed as in equation 3 and i_L as in equation 6. (In this case θ_1 and θ_2 are equal to the values of ωt which make equation $8=\phi_1$ while, due to the third line bc, θ_3 and, θ_4 should be similarly introduced, thus only equation 8 will be equal to ϕ_2.) From the nature of this and similar problems, only odd harmonics are considered. Substituting the expressions for ϕ and i_L of equations 3 and 6 in equation 7 and equating the coefficients of similar terms in both sides will give linear equations in A_1, B_1, A_3, B_3, etc., which can be solved by well-known methods leading to

$$\phi=A_1\cos\omega t+A_3\cos 3\omega t+A_5\cos 5\omega t+ \\ B_1\sin\omega t+B_3\sin 3\omega t+B_5\sin 5\omega t \tag{9}$$

Table I. Approximations of Coefficients

Coefficient	Second Approximation	Third Approximation
A_1	−1.111	−1.13
B_1	−0.144	−0.159
A_3	−0.0384	−0.0389
B_3	−0.01	−0.19
A_5	0.00057	−0.0011
B_5	−0.00157	−0.0028

Harmonics up to the fifth were found to be generally sufficient.

As a second approximation, θ_1, θ_2, θ_3, and θ_4 are recalculated from equation 9 instead of equation 8, and the corresponding values of A_1, B_1, A_3 . . . etc., can be deduced by a similar procedure. This process should be repeated until two successive values for θ_1, θ_2, θ_3, and θ_4 (or A_1, B_1, A_3, etc.) will be nearly unchanged.

By substituting 12×10^{-6},1/390, and 0.746 for A, B, and K in equation 7, Table I gives the second and third approximations of A_1, B_1, A_3, B_3, and A_5 and B_5.

Consider the third approximation

$$V=\frac{d\phi}{dt}=289\sin(\omega t-8°)-0.113\times \\ \cos(3\omega t+62°36')-0.0133\times \\ \cos(5\omega t+22°\ 42) \tag{10}$$

This example has been solved analytically and checked experimentally by Mostafa and Shishini.[8] Analytically they found

$$V=290\sin(\omega t-3°20')+0.104\cos(3\omega t- \\ 82°)+0.0126\cos(5\omega t-96°46') \tag{11}$$

Fig. 8 shows the experimental oscillograph which was given by them. In this illustration the supply voltage is also shown 180 degrees out of phase. Although equations 10 and 11 may differ in the coefficients, they have nearly the same shape as shown in Fig. 9. (Another example of this is seen from Fig. 4 where the B-H curve could be represented by different polynomial series with different coefficients of the similar terms.)

As the foregoing analysis is based on successive approximations, it will not always lead to correct results as previously mentioned, especially if the initial values are not close to the final required ones or considerable harmonics are produced. Therefore, there is a need for another method which does not depend on successive approximations.

In the example given, the values of θ_1 and θ_2 can be directly determined with reasonable accuracy by the use of another equivalent representation of the nonlinear given relation. The ϕ-i_L relation given in Fig. 7 will be represented by three straight lines, oa, ab, and bc, as shown in Fig. 10 in which oa is parallel to bc and ab is perpendicular to the i_L axis. In this way the term $(m_2-m_1)\,F_2(\omega t)$ of equation 6 will be cancelled. The result is that θ_1 and θ_2 can be determined without successive approximations as shown in Appendix II. (Sometimes more than one real value for θ_1 and θ_2 can be obtained. In this case more than one solution may exist; a phenomenon which was illustrated by many previous authors, e.g., Thomson[4] and Stoker.[6])

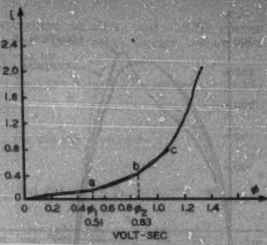

Fig. 7. Representation of I-φ curve in Fig. 3 by straight lines

With this second representation the solution of the previous example will be given by

$$v=258(\sin\omega t-0.3\cos\omega t+0.206\times \\ \sin 3\omega t+0.062\cos 3\omega t+0.000979\times \\ \sin 5\omega t-0.01121\cos 5\omega t) \tag{12}$$

Equation 12 is represented in Fig. 9 where it can be seen that it gives much better results. The second method of representation is similarly applied to the circuit shown in Fig. 11 (by separating the losses for the iron-cored coil the values of R' corresponding to the eddy-current losses can be determined). Neglecting the hysteresis effect for the time being, the differential equation will be

$$\left(1+\frac{R}{R'}\right)\frac{d^2\phi}{dt^2}+\frac{1}{CR'}\frac{d\phi}{dt}+R\frac{di_L}{dt}+\frac{i_L}{C} \\ =\omega V\cos\omega t \tag{13}$$

Fig. 8. Oscillogram for coil and supply voltages in Fig. 6. The latter is 180 degrees out of phase

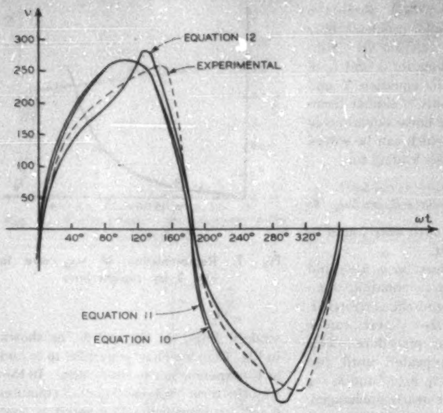

Fig. 9. Comparison between experimental and theoretical results for Fig. 6

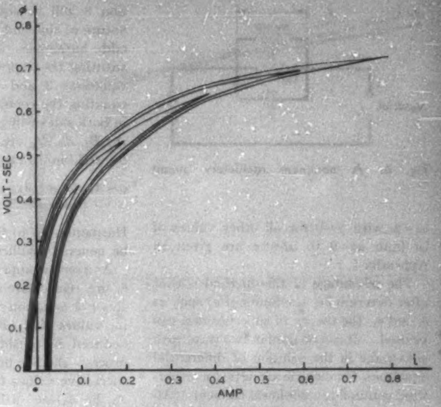

Fig. 12. φ-i loop curves for iron coil in Fig. 11

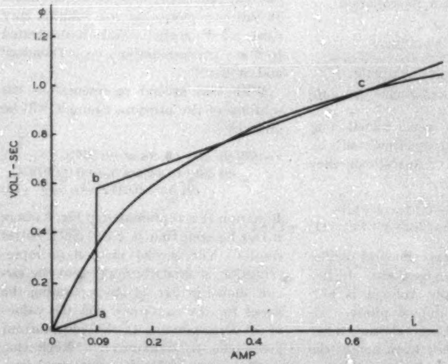

Fig. 10. Suggested method for representing φ-i curve in Fig. 3

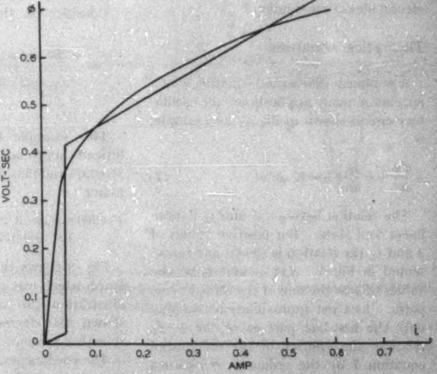

Fig. 13. Suggested representation of φ-i curve of Fig. 12

Working on the single-valued relation between ϕ and i_L which passes by the tips of the hysteresis loops (Fig. 12 shows the upper parts of such loops), the suggested representation would be as shown in Fig. 13 and it can be found that the following obtains

$$i=i_{R'}+i_L=0.29725\cos\omega t+0.0852\times\cos 3\omega t-0.09316\cos 5\omega t+0.1196\sin\omega t+0.19234\sin 3\omega t+0.05264\sin 5\omega t \quad (14)$$

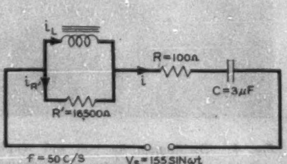

Fig. 11. A nonlinear oscillatory circuit

From equation 14 the rms value of $i=i_{\text{rms}}=0.282$ ampere. Experimentally $i_{\text{rms}}\doteq 0.26$ ampere, while its wave form is as shown in Fig. 14, where the supply voltage is also represented. From Fig. 15 it can be seen that equation 14 is in good agreement with the experimental results. In this example if it is required to take the hysteresis effect into consideration, the maximum value of i_L from equation 14 or Fig. 15 would equal to 0.62 ampere corresponding to $\phi_{\max}=0.693$ volt-second. From the area of the corresponding hysteresis loop and the frequency, the loss per second due to the hysteresis action would equal 3.865 watts which is equivalent to a resistance $R_{\text{hys}}=12{,}100$ ohms in shunt with R' (assuming the voltage on the iron-cored coil is not changed). This will lead to

$$i=0.2831\cos\omega t-0.00622\cos 3\omega t-0.09735\cos 5\omega t+0.1816\sin\omega t+0.2069\sin 3\omega t-0.0227\sin 5\omega t \quad (15)$$

Equation 15 is also represented in Fig. 15.

Fig. 14. Oscillogram for current and supply voltage in Fig. 11

The harmonics obtained in equation 14 or 15 are greater than 33 per cent. A similar result can be obtained if the supply voltage contains considerable harmonics. According to the author's knowledge, this is the only general solution found so far which can be used satisfactorily in the cases of such percentage of harmonics in the supply.

Conclusions

The suggested representation of the nonlinear single-valued relation is quicker than the other methods used before. It can be used to solve all types of nonlinear electric circuits, and similar cases, which contain a nonlinear element with great advantages, especially if the required results contain considerable harmonics. As the solutions given by other methods are restricted, Dr. Barrow has pointed out the importance of finding such a general solution.[2]

Appendix I

According to Fig. 16, *ab* is a part of curve $A_m \cos m\omega t$ when $m=1$. By Fourier analysis the curve *oa'abb'c* (and the similar ones when m equals other integer values) can be given by

$$a_{oc}+\Sigma a_{nc}\cos n\omega t+\Sigma b_{nc}\sin n\omega t \tag{16}$$

where

$$a_{oc}=\frac{A_m}{2\pi}\,\frac{\sin m\theta_2-\sin m\theta_1}{m}$$

$$a_{nc}=\frac{A_m}{2\pi}\left[\frac{\sin(n+m)\theta_2}{n+m}+\frac{\sin(n-m)\theta_2}{n-m}-\frac{\sin(n+m)\theta_1}{n+m}-\frac{\sin(n-m)\theta_1}{n-m}\right]\text{if } n\neq m$$

$$a_{nc}=\frac{A_m}{2\pi}\left[\theta_2-\theta_1+\frac{\sin(n+m)\theta_2}{n+m}-\frac{\sin(n+m)\theta_1}{n+m}\right]\text{if } n=m$$

$$b_{n,}=\frac{A_m}{2\pi}\left[\frac{\cos(n+m)\theta_1}{n+m}+\frac{\cos(n-m)\theta_1}{n-m}-\frac{\cos(n+m)\theta_2}{n+m}-\frac{\cos(n-m)\theta_2}{n-m}\right]\text{if } n\neq m$$

$$=\frac{A_m}{2\pi}\left[\frac{\cos(n+m)\theta_1}{n+m}-\frac{\cos(n+m)\theta_2}{n+m}\right]\text{if } n=m$$

According to Fig. 17, *ab* is a part of the curve $B_m \sin m\omega t$ when $m=1$. By Fourier series curve *oa'abb'c*, and similar curves when m equals other integer values, can be given by

$$a_{os}+\Sigma a_{ns}\cos n_{\omega}t_{ns}+\Sigma b_{ns}\sin n\omega t \tag{17}$$

where

$$a_{os}=\frac{B_m}{2\pi}\,\frac{\cos m\theta_1-\cos m\theta_2}{m}$$

$$a_{ns}=\frac{B_m}{2\pi}\left[\frac{\cos(n-m)\theta_2}{n-m}-\frac{\cos(n-m)\theta_1}{n-m}-\frac{\cos(n+m)\theta_2}{n+m}+\frac{\cos(n+m)\theta_1}{n+m}\right]\text{if } n\neq m$$

$$a_{ns}=\frac{B_m}{2\pi}\left[\frac{\cos(n+m)\theta_1}{n+m}-\frac{\cos(n+m)\theta_2}{n+m}\right]\text{if } n=m$$

$$b_{ns}=\frac{B_m}{2\pi}\left[\frac{\sin(n-m)\theta_2}{n-m}-\frac{\sin(n+m)\theta_2}{n+m}-\frac{\sin(n-m)\theta_1}{n-m}+\frac{\sin(n+m)\theta_1}{n+m}\right]\text{if } n\neq m$$

$$=\frac{B_m}{2\pi}\left[\theta_2-\theta_1-\frac{\sin(n+m)\theta_2}{n+m}+\frac{\sin(n+m)\theta_1}{n+m}\right]\text{if } n=m$$

According to Fig. 18, *ab* is a part of a straight line parallel to the x axis and its ordinate $=C_m$. By Fourier analysis, curve *oa'abb'c* is given by

$$a_o+\Sigma a_n\cos n\omega t+\Sigma b_n\sin n\omega t \tag{18}$$

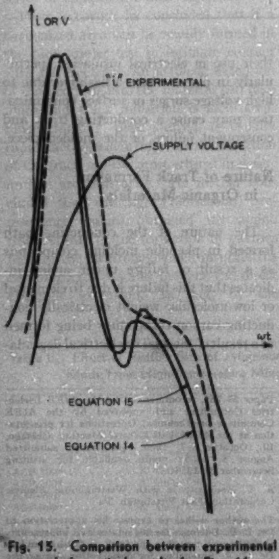

Fig. 15. Comparison between experimental and theoretical results for Fig. 11

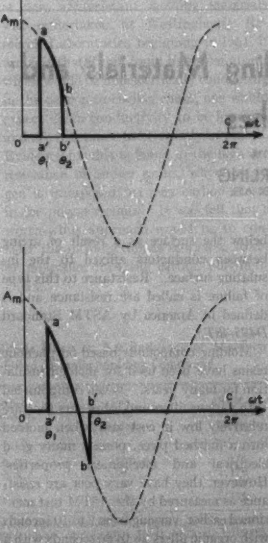

Fig. 16. A part of the curve $A_m \cos wt$

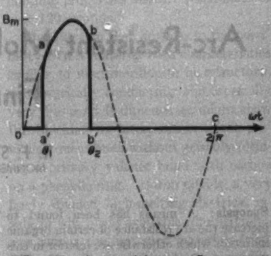

Fig. 17. A part of the curve $B_m \sin wt$

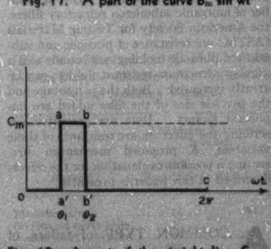

Fig. 18. A part of the straight line $C_m=$ constant

where

$$a_0=\frac{C_m(\theta_2-\theta_1)}{2\pi}$$

$$a_n=\frac{C_m}{\pi}\,\frac{\sin n\theta_2-\sin n\theta_1}{n}$$

$$b_n=\frac{C_m}{\pi}\,\frac{\cos n\theta_1-\cos n\theta_2}{n}$$

Appendix II

From Fig. 7, the $\phi-i_L$ relation can be expressed as follows:

$$\phi=0.764\,i_L \text{ from } i_L=-0.09 \text{ ampere to } i_L=0.09 \text{ ampere} \quad (19)$$

$$\left.\begin{aligned}&\phi=0.764\,i_L+0.515 \text{ when } i_L>0.09 \text{ ampere}\\ &\phi=0.764\,i_L-0.515 \text{ when } i_L<-0.09 \text{ ampere}\end{aligned}\right\} \quad (20)$$

Considering the harmonics up to the fifth only, i_L can be put in the form:

$$i_L=A_1\cos\omega t+A_3\cos 3\omega t+A_5\cos 5\omega t+B_1\sin\omega t+B_3\sin 3\omega t+B_5\sin 5\omega t \quad (21)$$

If θ_1 and θ_2 are the values of ωt which make i_L in equation 21 $=0.09$, then by the use of equations 3, 6, and Appendix I:

$$\begin{aligned}\phi=\;&0.764(A_1\cos\omega t+A_3\cos 3\omega t+A_5\cos 5\omega t+B_1\sin\omega t+B_3\sin 3\omega t+B_5\sin 5\omega t)+\\ &\frac{2\times 0.515}{\pi}\left\{(\sin\theta_2-\sin\theta_1)\cos\omega t+\frac{(\sin 3\theta_2-\sin 3\theta_1)}{3}\cos 3\omega t+\frac{(\sin 5\theta_2-\sin 5\theta_1)}{5}\cos 5\omega t+\right.\\ &(\cos\theta_1-\cos\theta_2)\sin\omega t+\frac{(\cos 3\theta_1-\cos 3\theta_2)}{3}\sin 3\omega t+\left.\frac{(\cos 5\theta_1-\cos 5\theta_2)}{5}\sin 5\omega t\right\}\end{aligned} \quad (22)$$

By substituting equations 21 and 22 in equation 7 and equating the coefficients of similar terms in both sides (A, B, and K are equal to 12×10^{-4}, 1/390, and 0.746, respectively) A_1, B_1, A_3, etc., will be given by

$$\left.\begin{aligned}A_1&=-0.885-0.000202(\sin\theta_2-\sin\theta_1)-0.51(\cos\theta_1-\cos\theta_2)\\ B_1&=0.775-0.000202(\cos\theta_1-\cos\theta_2)+0.51(\sin\theta_2-\sin\theta_1)\end{aligned}\right\} \quad (23)$$

$$\left.\begin{aligned}A_3&=-0.1721(\sin 3\theta_2-\sin 3\theta_1)-0.094(\cos 3\theta_1-\cos 3\theta_2)\\ B_3&=-0.1721(\cos 3\theta_1-\cos 3\theta_2)+0.094(\sin 3\theta_2-\sin 3\theta_1)\end{aligned}\right\} \quad (24)$$

$$\left.\begin{aligned}A_5&=-0.0939(\sin 5\theta_2-\sin 5\theta_1)-0.00121(\cos 5\theta_1-\cos 5\theta_2)\\ B_5&=-0.0939(\cos 5\theta_1-\cos 5\theta_2)+0.00121(\sin 5\theta_2-\sin 5\theta_1)\end{aligned}\right\} \quad (25)$$

From equations 21, 23, 24, and 25, considering the cases when $i_L=0.09$ ampere while $\omega t=\theta_1$ or θ_2, equations 26 and 27 can be deduced:

$$\begin{aligned}&1.16\sin(\theta_1-49.5^\circ)-0.000202\times\sin(\theta_2-\theta_1)+0.51\cos(\theta_2-\theta_1)-0.172\times\sin 3(\theta_2-\theta_1)+0.094\cos 3(\theta_2-\\ &\theta_1)-0.0939\sin 5(\theta_2-\theta_1)+0.0012\times\cos 5(\theta_2-\theta_1)-0.6952=0\end{aligned} \quad (26)$$

$$\begin{aligned}&1.16\sin(\theta_2-49.5^\circ)-0.000202\times\sin(\theta_2-\theta_1)-0.51\cos(\theta_2-\theta_1)-0.172\times\sin 3(\theta_2-\theta_1)-0.094\cos 3(\theta_2-\\ &\theta_1)-0.0939\sin 5(\theta_2-\theta_1)-0.0012\times\cos 5(\theta_2-\theta_1)+0.5152=0\end{aligned} \quad (27)$$

Assuming different values for $(\theta_2-\theta_1)$ in equations 26 and 27, the corresponding values of θ_1 and θ_2 can be deduced, and from which another value of $(\theta_2-\theta_1)$ can be obtained. The difference between the assumed and deduced values of $(\theta_2-\theta_1)$ are tabulated against the assumed $(\theta_2-\theta_1)$. The required value is that which makes the corresponding difference equal to zero. In this example, θ_1 and θ_2 are found to be equal to 129.1 and 268.6 degrees, i.e., −91.4 degrees, respectively.

Arc-Resistant Molding Materials and Finishes

R. F. STERLING
NONMEMBER AIEE

Synopsis: A means has been found to increase the arc resistance of certain organic materials which otherwise are inferior in this property. By incorporating any of a number of inorganic submicron refractory fillers, the American Society for Testing Materials (ASTM) arc resistance of phenolic and substituted phenolic molding compounds and a number of non-arc-resistant finishes can be greatly increased. Both the percentage and the particle size of the filler added are important factors. Data are presented describing the effect on arc resistance of these variables. A proposed mechanism presenting a possible explanation for the effects described in this paper is presented.

A COMMON TYPE of failure of organic electrical insulation is due to a conducting path forming on or just below the surface as a result of arcing between conductors affixed to the insulating surface. Resistance to this type of failure is called arc resistance and is defined in America by ASTM Standard *D495-48T*.[1]

Molding compounds based on phenolic resins have been used for molded insulation for many years. When compounded with various fillers and lubricants they are relatively low in cost and, when molded into a finished piece, possess many good electrical and mechanical properties. However, they have very poor arc resistance as measured by the ASTM test mentioned earlier, varying from 2 to 10 seconds with organic fillers up to 60 seconds with a glass filler.[2] This has seriously limited their use in electrical insulation, particularly in places where a flashover due to high-voltage surges or surface contamination may cause a conducting track and consequent failure of the molded piece.

Nature of Track Formation in Organic Materials

The nature of the conducting path formed in phenolic molding compounds as a result of failure under arcing indicates that this failure is due to elemental or low-molecular-weight electrically conducting carbon compounds being formed as a result of thermal or electrical degrada-

tion. The very high carbon content, about 80 per cent (%) by weight, and extent of carbon-to-carbon bonding render phenolics particularly susceptible to arc failures. This relationship between a phenyl ring structure and low arc resistance was noted by Warren[3] who emphasized the superior arc resistance of alkyl groups to phenyl groups when substituted on silicone polymer chains.

Olyphant,[4,5] using high-speed photographic methods, studied the tracking process ("tracking" in this case refers to a conducting path due to an external arc) and the effect on this process of various testing conditions. He examined the mechanisms of both track initiation and track propagation in a number of materials, including mineral- and wood-flour-filled phenolics, alpha-cellulose- and asbestos-filled melamine, alpha-cellulose-filled urea, glass-bonded mica, and a series of compressed filler materials.

From his work he concluded that if a carbonized area can be readily formed in the piece under test in intimate contact with the electrode, an artificial extension of the electrode into the material can take place and track initiation is facilitated. Since tracking, once started, is usually rapid, factors which influence the initiation of the track are the most critical in determining arc resistance. He further concluded that the high (130-second) arc-resistance values obtained for amino resins is due to the formation of cavities next to the electrodes which insulate the carbonizing areas and prevent the direct electrode extension. In fact, by the simple means of raising the electrodes as little as 0.01 inch from the surface of the test piece, he was able to obtain arc-resistance values for phenolic molding materials of 120 seconds or more, while under the same conditions of raised electrodes melamine molding materials still failed between 130 and 140 seconds.

Experimental Procedure and Results

When the problem of the development of new arc-resistant molding materials was undertaken at Westinghouse Research Laboratories beginning in 1951, it was felt that if one could interpose atoms which would be nonelectrically conducting in the carbon-to-carbon chain, one would expect chain conductivity to be lowered, and arc resistance to be greatly increased. Evidence for this is found in the high arc resistance of amino resins, where nitrogen is interposed between carbon atoms in the polymer chain. It was felt that a worth-while approach would be to consider the introduction of inorganic atoms or molecules into the carbon polymeric chain.

Following this thought, a literature search disclosed that previous investigators, especially Hendricks,[6] had reacted aniline with montmorillonite, a complex inorganic molecule, to form a compound in efforts to obtain a polymeric soil stabilizer. If a copolymer could be formed of aniline montmorillonite, phenol, and formaldehyde which was moldable under heat and pressure, it might have high arc resistance, due to the relatively bulky inorganic montmorillonite molecule preventing a continuous carbon path from forming after arcing.

EXPERIMENTAL PROCEDURE

Following Hendricks procedure, aniline montmorillonite was made and identified. This, when blended with modified phenolic resins previously made, showed good molding properties and arc resistances of over 120 seconds.

The question then arose as to the possibility that a material with characteristics similar to montmorillonite in refractory, nonelectrically conducting, and especially very fine particle dimensions, might show the blocking or interposition effect previously mentioned without actually forming a primary valence bond with carbon on a phenolic ring. Boron nitride, a very finely divided high-melting electrical insulator which was available commercially, was among the first such materials tried. This showed a great increase in arc resist-

Table II. Effect of Particle Size of Aluminum Silicate Fillers on Arc Resistance of Moldings Made From High-Temperature Mineral-Filled Phenolic Molding Compound

ance, even better than the aniline montmorillonite modified materials had shown. The work was then extended, first to other resins, then to other submicron-diameter refractory fillers, until the fact was established that quite a number of these materials would improve ASTM arc resistance in phenolic molding compounds. The work was later extended to cover coatings and finishes.

The procedure followed in compiling the data shown in Tables I–III report was as given in the following.

The molding resin was first compounded. This was done in either of two ways. The first way was simply to dry-mix the submicron fillers into a commercial wood-flour or asbestos-filled molding material and then to compound these fillers into the molding material by milling on steam-heated differential rolls at temperatures of 100–115 C (degrees centigrade). The second way was to start with either a commercial or a laboratory-prepared novolak and add the required amount of hexamethylenetetramine, lubricants, and auxiliary fillers to give the moldability and mechanical properties desired before milling. It was found very early in the program that this milling was necessary to insure uniform distribution on a micro scale of the filler into the molding compound. The resultant blanket of molding material as removed from the rolls was then broken up and ground in a Wiley hammer mill to a fineness passing through a 16-mesh screen. The resultant coarse powder was then placed in airtight glass jars and stored until molding. The molding itself was largely performed on a hand-operated Carver laboratory press in a 2-inch disk mold, the disks being 2 inches in diameter and about 1/8 inch thick. More promising formulations were then molded into pieces of operating equipment such as circuit breakers and meter bases for further testing.

ASTM arc-resistance tests were carried out on the various pieces on the testing equipment at Westinghouse Research Laboratories. The more promising specimens were checked by other operators on the ASTM equipment at the Westinghouse Engineering Laboratories.

Experimental Results

It can be observed from Tables I and II that the improvement in ASTM arc resistance of otherwise non-arc-resistant phenolic molding compounds is roughly inversely proportional to the particle diameter, with slight improvement detectable at 5-micron particle diameter and increasing arc resistance as the ultimate particle diameter of the filler is reduced to 0.5 micron or less. Table III shows that a beneficial effect on arc resistance is detectable when the fillers are added in quantities as low as 1% by weight. Composition of the finely divided filler is apparently not critical if requirements of thermal stability and electrical insulation are met. Oxides of silicon, aluminum, zirconium, titanium, and beryllium are available in submicron particle diameters, and have all demonstrated this effect on ASTM arc resistance, as well as the aniline montmorillonite and boron nitride mentioned earlier. For a given particle size and percentage of a given filler, the improvement in arc resistance is affected by the other fillers present. For example, 10% of aluminum silicate of 0.5-micron mean particle diameter increases the arc resistance of wood-flour-filled phenolic resins to 120–130 seconds and of asbestos-filled phenolic resins to over 180 seconds.

Because of a lack of availability of a range of particle sizes of many of the refractory materials, the tables illustrate the effect on arc resistance of silica and aluminum silicate, which are available in a well-classified range of particle sizes.

The effect of some of these fillers on the arc resistance of various finishes is shown in Tables IV and V.

Discussion of Results

The following explanation seems probable for the results described in this paper. The ASTM test for arc resistance utilizes a high-voltage low-current arc, with the electrodes so placed and shaped that the arc drawn between them is bowed upward and failure in phenolic-molded products always occurs by initiation of a conducting track at one of the electrodes, followed by rapid extension of what is then a point electrode across the surface of the molded piece. Olyphant's study had shown that in phenolics track growth occurred only on

Fig. 3. Conducting track immediately after initiation at electrode on left

Fig. 4. Conducting track completed

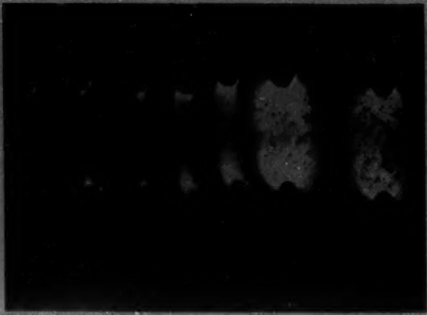

Fig. 5. Progressive formation of refractory mat on phenolic molding after 15, 30, 60, 90, 120, and 180 seconds, and failure

Fig. 6. Same molding as Fig. 5, lighted to illustrate interference patterns formed probably due to erosion of organic molding by arcs

the half-cycle when the advancing point forming the conducting track was negative with respect to the stationary electrode, the arc remaining fixed in length on the half-cycles when the advancing point forming the track was positive. If, however, track initiation can be prevented, track growth cannot begin. To prevent track initiation in phenolic resins as described in this paper, not only must the refractory filler be of sufficiently fine particle diameter, but it must also be uniformly distributed in the molding compound. It has therefore been found necessary to incorporate the filler by milling on hot differential rolls to obtain the desired high arc resistance. Dry blending of these fillers into the molding resin has proved inadequate to obtain uniformly high arc resistance.

If the rate of degradation of the phenolic polymer at the electrode tip can be reduced to the point where all the products of degradation of the carbon-rich phenolic are oxidized and volatilize off as gaseous carbon monoxide or carbon dioxide, track initiation can be prevented. This point can be illustrated by Figs. 1 and 2. Fig. 1 is a hypothetical cross section of a molded phenolic piece using conventional filler. Fig. 2 is the same cross section using an equal weight of submicron filler. The fillers in both cases are assumed to be roughly spherical in shape.

Although, assuming that the shapes of large and small particles of filler are the same, the resin-to-filler ratio is the same in the two illustrations, it will be seen that at any time there is a much larger and thicker volume of pure resin available to break down thermally and form a conducting carbonaceous residue in the case illustrated by Fig. 1 than that illustrated by Fig. 2. If the pieces illustrated are subjected to the ASTM arc-resistance test, the arc, particularly near the electrode tip, rapidly decomposes the resin present on the surface of the molding. In the case shown in Fig. 1, the resin breaks down thermally to low-molecular-weight carbonaceous residues which, because of insufficient oxygen present, do not vaporize and therefore remain in place and very rapidly form a conducting path. This is shown in Fig. 3, where the arc has carbonized a portion of the resin immediately adjacent to the electrode. This conducting portion then forms an extension of the electrode and the track will, in a few more cycles, extend to the other electrode, giving the characteristic thin wire-like track shown in Fig. 4. The spots of greater decomposition on the track are those described by Olyphant[4,5] as due to the half-cycle in which the track is positive with respect to the other electrode and not growing, track growth only occurring on the half-cycles when the track is negative to the other electrode. In the case shown in Fig. 2, however, the resin immediately adjacent to the electrode tips will again break down thermally to low-molecular-weight carbonaceous residues when the arc is applied. However, because of the presence of these residues in relatively thin films between particles, oxidation occurs and the residue is vaporized. A second beneficial effect is observed as this process continues under repeated arcs. With the vaporization of the inorganic material present, the inorganic material appears to remain in place, forming a porous insulating mat of refractory material. This may be seen in Figs. 5 and 6 which show a conventional asbestos-fiber- and wood-flour-filled phenolic to which 10% by weight of boron nitride was added. Fig. 5, with the photograph taken normal to the surface, shows the mat formation, beginning at the left, after 15, 30, 60, 90, 120, and 180 seconds, and failure, which occurred at 185 seconds. This failure occurred by a track forming around the mat at the edge, at the extreme right side of Fig. 5.

Fig. 6 shows the first six tracks of the same test piece. It is an attempt to indicate the thickness of the insulating mat remaining after the organic portion of the molding is vaporized. An interference pattern, characteristic of thin films, appears first near the electrodes and then gradually extends toward the other electrode. As shown in Fig. 6, an interference pattern can be seen between the resin subsurface and the refractory mat surface after 15, 30, and 60 seconds of the ASTM test, but after 90 seconds the film is so thick that no interference can be discerned except at one edge.

Conclusions

A means has been found to increase the arc resistance of certain organic materials which otherwise are inferior in this property. By incorporating any of a number of inorganic submicron refractory fillers, the ASTM arc resistance of phenolic and substituted phenolic molding compounds and a number of non-arc-resistant finishes can be greatly increased. A postulated mechanism explaining the observed phenomenon is proposed. The major conclusions to be drawn from this work are as follows:

1. The addition of inorganic refractory fillers of sufficiently fine particle diameter is a means which can be used to increase the ASTM arc resistance of phenolic and substituted phenolic resins, as well as certain otherwise non-arc-resistant finishes. These fillers, which include oxides of silicon,

aluminum, beryllium, zirconium, and titanium, combinations of these in the form of silicates, titanates, and zirconates, as well as boron nitride and aniline montmorillonite, are, for the most part, quite inexpensive, and when added in amounts up to 10% by weight, do not seriously affect the mechanical properties of the molded piece.

2. The improvement in the ASTM arc resistance of phenolic and substituted phenolic molding compounds, as well as certain otherwise non-arc-resistant finishes, is an inverse function of particle diameter of these refractory inorganic fillers. At particle diameters above approximately 5 microns, the effect described essentially disappears.

3. The beneficial result of these fillers is a function of percentage content in the molded article or finish. Beneficial results were observed at as low as 1%-by-weight filler; however, 10% addition provided considerably greater arc resistance.

4. In use of this means of improving ASTM arc resistance, the importance of uniform dispersion of the filler in the molding compound or enamel is critical. Differential roll milling is required to obtain the effects described in this paper.

5. Molding materials and finishes possessing high arc resistance intrinsically, such as the amino resins, are not markedly improved in this quality by addition of the fillers described in this paper.

6. The data and conclusions presented in this paper are all based on results obtained on equipment testing to ASTM Standard *D495-48T*, with currents at 10 milliamperes, and effects of a range of higher currents such as are involved in power apparatus have not been investigated. No equipment has been standardized or has achieved wide usage for testing arc resistance at higher power levels.

A Transistorized Time-Division Multiplex Telegraph Set

F. D. BIGGAM
ASSOCIATE MEMBER AIEE

Synopsis: Increased usage of radio-teletypewriter communication has widened the demand for facilities for multiplexing teletypewriter channels on a single radio channel, for economy of frequency spectrum and equipment. Many of the potential applications of multiplex require smaller and lighter equipment than heretofore available, with unusually high reliability. This paper describes a developmental time-division multiplex equipment which, through the use of transistors, has only 20 per cent of the volume, 20 per cent of the weight, and 5 per cent of the power consumption of the equivalent electron-tube set now in service. The set is packaged for maximum operating convenience and serviceability in the field.

THE transistorized multiplex is a completely transistorized 4-channel time-division multiplex telegraph terminal set. It is functionally similar to, and compatible with the *AN/FGC-5* electronic multiplex,[1] which has been in general use since 1950 on long-haul high-frequency radio circuits. In all active electronic functions such as switching and amplification, as well as in the power supply, only solid-state devices are employed. There are no vacuum tubes in the set.

The equipment is designed as an integral part of a time-division multiplex system wherein two, three, or four start-stop telegraph channels are combined for transmission over a common communication circuit. It occupies approximately one fourth of the physical volume of the vacuum-tube set, as is apparent in Fig. 1. The complete send-receive terminal is housed in one 36-inch-high cabinet and weights only 275 pounds, as compared to 1,450 pounds for the electron-tube equivalent. It consumes only 1/20 as much electric power in order to perform identical functions. The weight, size, and power savings are made possible by the application of transistors and solid-state devices. The set contains over 550 transistors and over 700 germanium diodes.

History

The use of time-division multiplex equipment in commercial telegraph service dates back as early as the turn of the century. The original multiplexes were motor driven and mechanically operated. Electromechanical systems were subsequently adapted for use on radio-telegraph circuits during World War II, where the multiplexing of channels served both to increase circuit capacity and to make more efficient use of the frequency spectrum. With the development of frequency-shift keying for radio transmitters, and of improved radio-receiving systems, interest in time-division multiplex was further stimulated. Since electromechanical designs were difficult to maintain, were hard to phase, and had a low order of frequency stability, a new approach was dictated. The electronic multiplex in general use today was developed as a result of this need. Over 500 of these sets have been manufactured. They are presently in service throughout the world, capably performing the function for which they were designed.

More recently, because of further improvements which have been made in transmission techniques, and of even greater traffic loads, new design requirements for time-division multiplex facilities have been created. In some applications, an equipment of minimum size, weight, and power consumption is demanded. Among these are mobile and shipboard installations. Investigations were therefore made into means for better meeting these requirements, which were imposed by this potential demand. As a result the transistorized multiplex equipment described here was designed; four developmental models are presently undergoing field trials.

The Multiplex System

The transmitting multiplex responds to input telegraph signals of the standard 7.42-unit (Baudot) code. These signals may be supplied either from a continuous

transmitting device such as a transmitting distributor, or from a teletypewriter keyboard. Fig. 2 shows four typical input signals. Each input character consists of a start element followed by five code pulses and a stop element. The start and stop elements are always the same, "space" (no current) for the start pulse and "mark" (current) for the stop pulse, while each of the five code elements may be either mark or space, depending upon the character being transmitted. The input signals are fundamentally nonsynchronous. More accurately, successive pulses within any one character are transmitted and received synchronously, but the timing of successive characters is not synchronous, and may be completely random. The function of the start and stop pulses is to resynchronize, or rephase the receiving printer with the received signal at the beginning of each character. Other than to establish a reference point, the start and stop pulses contain no information.

The multiplex, on the other hand, is a fully synchronous system. The receiving terminal is maintained in step with the transmitting terminal, in both frequency and phase, by a frequency standard which is independent of the signal being transmitted. There is therefore no need to transmit synchronizing information at the start of each character. Consequently, in forming the multiplex signal only the five code elements are used, the start and stop pulses having been dropped at the transmitting end. A sixth pulse is added by the multiplex, the function of which will be described. At the receiving terminal, the signal is reconstituted by the automatic insertion of the start and stop pulses.

Since start-stop inputs to the multiplex may be of slightly varying transmission rates and have no direct phase relationship between channels, it is necessary that multiplex transmission be slightly faster than the incoming start-stop signals. This results in a constantly sliding or varying phase relationship between the start-stop and multiplex signals, with the multiplex signal continuously gaining on the start-stop signal. Occasionally the multiplex signal will get sufficiently ahead of the start-stop signals so that it must pause to allow the start-stop signal to catch up. This is accomplished by the automatic insertion of multiplex "blank," which is an all-spacing group. Since the blank combination is considered a true character in the start-stop code, it is necessary for the multiplex receiver to distinguish between code blanks which occur when the channel is idle, or because of this speed difference, and blanks which should be transmitted over the channel and delivered to the distant receiving circuit, because they were among the start-stop signals received from the originating transmitters. To accomplish this, a sixth element has been added to the multiplex signal code. This element is made marking for each transmission of character combination, and spacing for each transmission of an idle signal, or time differential blank.

Since four characters must be transmitted over a single circuit during the time ordinarily required by one, they must be compressed with respect to time so that each channel is transmitted during approximately one fourth of the time necessary for its initial generation. Fig. 2 shows the multiplex signal formed by the four start-stop inputs. Each channel is composed of fine code elements followed by the sixth pulse previously discussed. The multiplex signal shown is further modified before transmission by the inversion of certain pulses. These pulses are sent out as space when intended to be mark, and mark when space, in order to provide mark-space transitions during transmission of an idle signal. These transitions are necessary for synchronizing purposes. At the receiving terminal they are reinverted to their proper polarity.

A simplified block diagram of a transmitting and receiving multiplex system is shown in Fig. 3. At the left side, telegraph transmitters deliver start-stop signals to the individual transmitting group telegraph code converters. It is the function of the code converters to assemble the input information, which is in serial form, and present it to the multiplexer in parallel binary form. The multiplexer sweeps over the outputs of the code converters, channel by channel, picking up a complete character in turn from each converter at the multiplex frequency rate. The multiplex operating speed is controlled by the frequency standard, which has as its heart a transistorized crystal oscillator circuit. Impulses generated by the crystal oscillator and the various dividing circuits are used to step the multiplexer at the proper rate. By varying the pulse division ratio, the equipment may be switched to operate with inputs of either two, three, or four channels, or to accommodate telegraph speeds of 60, 75, or 100 words per minute, depending upon traffic requirements and radio-frequency propagation conditions. Multiplex outputs may be either keyed tone or 60-milliampere d-c signals. These signals are applied to the external transmitting equipment.

At the receiver, the demultiplexer performs functions complementary to those of the multiplexer. It separates the information and routes it to the proper code converter. The converters examine the input signal and, provided a character transmission has been recognized, begin the process whereby the start-stop signal is reconstituted and regenerated. The sixth

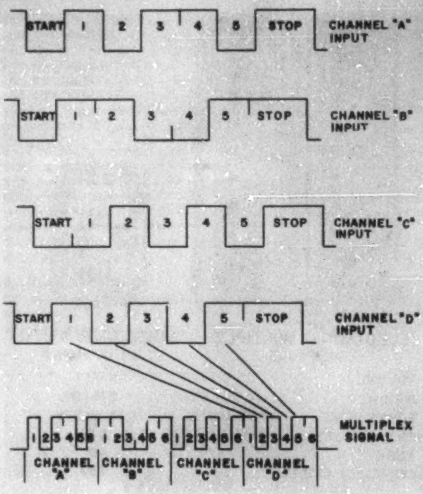

Fig. 2. Composition of the multiplex signal: Four start-stop signals are compressed with respect to time and transmitted channel by channel

pulse, which is used only to recognize the presence of a bona fide blank transmission, is dropped. The start and stop elements are added to the five code pulses and the signal is read out at telegraph speed.

The frequency standard at the receiving station performs a function identical to that of the transmitting group, except that its effective drive must be modified in the receiving group in order to maintain synchronism with the transmitting group. This is accomplished by a unique synchronizing circuit which operates on a digital basis. By noting the time location of space-to-mark transitions of the incoming multiplex signal, the exact phase relationship between the incoming signal and the demultiplexer drive is established. Synchronizer action is accomplished by adding or subtracting drive pulses in discrete steps until a proper time-phase relationship is achieved. This system of synchronizing permits the use of a single crystal oscillator to drive both the transmitting and receiving groups in a given location, since the frequency of the crystal oscillator remains fixed. The correction rate may be noted on the front panel by the flashing of a neon lamp. The frequency of these corrections is limited to a maximum value, which may be varied from 6.25 pulses per second, to one pulse per 20 seconds, by means of a synchronizing rate-control switch. The action of the synchronizer may therefore be slowed during poor signal periods. Since the synchronizer responds to changes in phase relationship between mark-space signal transitions of the incoming multiplex signal, it will attempt to establish as in-phase relationship, not only with normal signals, but with all extraneous bursts of noise and distortion which may be received. By limiting the maximum number of correction pulses generated by the synchronizer per unit time, it is possible to average out effectively these extraneous pulses, correcting only for frequency drift between the transmitting and receiving crystal oscillators.

In addition to the establishment of a time-phase relationship between the incoming signal and the demultiplexer drive, the receiver must be placed in proper channel register with the transmitter. That is, the proper information must be routed to the proper channel by the demultiplexer. With *A* channel transmission disabled, operation of a phasing button causes a train of drive pulses to be generated which add to the demultiplexer drive in order to advance its phase. The phasing pulses are automatically stopped when proper channels come into register.

Circuit Description

Transistors have characteristics which make them particularly suitable for use in equipments of this type. As switches, their very high resistance when "off" and practically zero resistance when "on," make them extremely useful, and as storage elements they store information at very low power levels.

Point-contact transistors are used in the equipment along with the more common junction type. Characteristics of point-contact transistors, which enable the realization of emitter to collector current gains greater than unity, greatly simplify the design of certain of the circuits.

There are several basic circuits which are employed to accomplish the necessary switching and logic functions. Among them are the ring distributor, storage, start-stop oscillator circuits, and the power supply. Since these circuits are typical of those employed, they will be described in the following paragraphs.

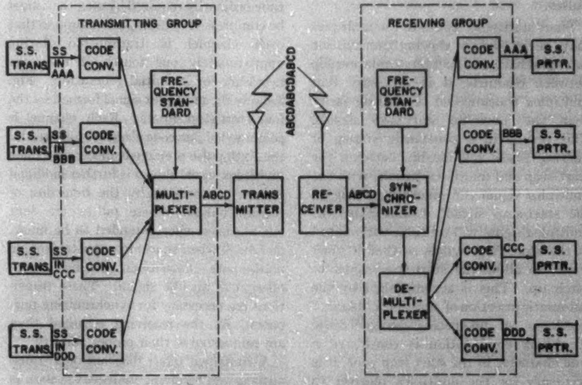

Fig. 3. Simplified block diagram, multiplex terminal set

RING DISTRIBUTOR

The ring distributor may be thought of as the basic circuit of the transistor multiplex. In addition to its basic distribution function, it is employed in the equipment as a frequency divider. There are 21 separate ring distributors in the equipment. A 3-element ring is shown in Fig. 4. While only three elements are shown, the ring may be connected in any configuration ranging from two to a very large number. Rings of this type have been reliably operated with as many as 26 stages, and indications are that an even greater number of stages could be connected if desired. However, the number of stages per ring varies from three to seven in the transistor multiplex.

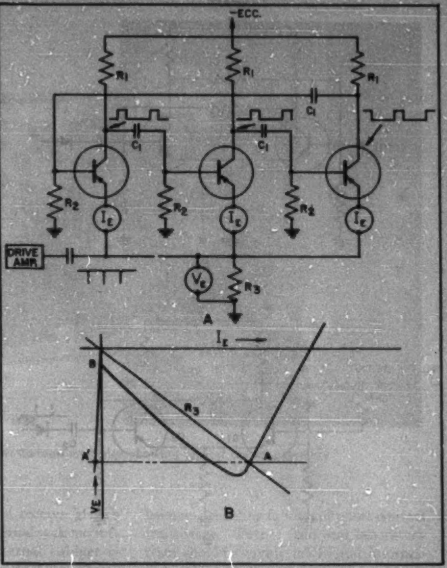

Fig. 4. Ring distributor

A—3-element ring distributor

B—Emitter input negative resistance characteristic of ring distributor element

The point-contact transistor, which is a highly nonlinear device for large signal operation and has an emitter-collector current gain greater than unity, is utilized in the basic ring circuit to accomplish the sequential switching function. With power applied to the circuit of Fig. 4(A), the distributor element with the highest combination of reverse collector-base current (I_{co}) and emitter current amplification (alpha) conducts into saturation. Current flowing through the common emitter resistor *R3* develops a voltage which when applied to the emitters of the off elements, biases them sufficiently in the reverse direction to prevent their conduction. Fig. 4(B) shows the input negative resistance characteristic curve of emitter voltage and emitter current for a typical ring element. When conducting, the element is stable at point *A*. Because the emitter resistor *R3* is common to both on and off elements, the off elements are held at point corresponding to a very slightly negative emitter current. The off ring elements are thus maintained in that condition by a bias voltage equal to *BA'*.

The distributor is stepped from one conducting element to the next by the following means: A negative drive pulse is applied to the common emitter connection which causes the conducting element to switch to the nonconducting state. When the collector voltage of the on element switches from slightly negative to highly negative, a differentiated negative wave form is passed through *C1*, and impressed on the base resistor of the following stage. When the stepping or triggering pulse is removed, the primed stage conducts into saturation.

This circuit, because of its basic simplicity, has made the application of point-contact transistors very practical. Only slightly over three components per stage, besides the transistors, are required.

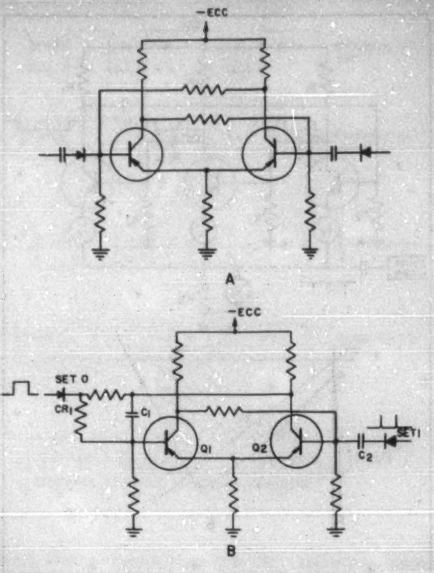
Because the circuit is arranged to be basically monostable, and therefore not dependent upon the interception of the emitter load line (*R3*) more than once with the emitter input characteristic curve of Fig. 4B, very satisfactory operating margins are achieved without adjustment of the circuit constants. No stabilization circuits are required. This circuit was designed to operate with transistors which have emitter-to-collector current gains as low as 1.8, and which allow reverse current flow (I_{co}) at 20 volts and 60 degrees centigrade to be as high as 3 milliamperes. The −20-volt operating voltage permits a 10-volt signal excursion between off and on, and forms the standard to which the voltage swings of all other circuits are matched.

STORAGE

Binary storage of information is accomplished by the use of Eccles-Jordan *p-n-p*-type junction transistor flip-flops as shown in Fig. 5(A). All storage, and many of the switching and timing circuits, are of this type. Triggering is accomplished by a positive going pulse applied to the base of the conducting element driving it to its off condition. The circuit is designed so that output levels will be compatible with that of the ring distributor circuit previously discussed. Voltage swings from −6 volts in the on to −16 volts in the off condition are therefore obtained.

Junction transistors used are generally low-frequency response units having alpha cutoff frequencies of 1 megacycle. Switching requirements were not sufficiently severe to warrant the use of higher frequency units. Grounded emitter current gains of as low as 30 may be tolerated in the circuits. The maximum reverse current at room temperature was specified as 15 microamperes.

A unique application of the basic storage circuit is shown in Fig. 5(B). At certain periods during operation of the equipment it becomes necessary for this circuit to act either as a bistable flip-flop, or as a monostable univibrator. Ordinarily the triggering, or set *1*, drive arrives prior to the reset, or set *O* pulse, in which case the circuit functions as a normal binary. However, at other times the set *O* pulse actually arrives prior to the set *1* pulse. It is necessary during these periods for the reset pulse to prime the stage in order that, upon the receipt of the triggering pulse, an output is obtained, and, after a timed interval, the circuit is automatically returned to the original condition. The desired function is controlled by the potential applied to the circuit through diode *CR1*. When the



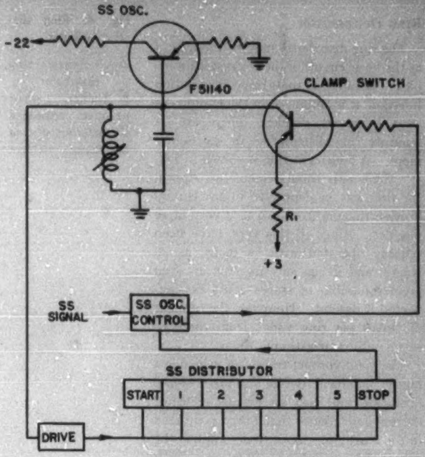


Fig. 5 (left). Binary storage

A—Binary storage element
B—Modified binary, bistable-monostable circuit

Fig. 6 (above). Start-stop oscillator and control

potential applied is most negative, *CR1* is biased in the reverse direction and is prevented from affecting the operation of the circuit. When a drive pulse is applied to the base of *Q2*, assuming *Q2* is conducting, the circuit will trigger, with *Q2* becoming nonconducting and *Q1* conducting. The flip-flop therefore operates in the conventional manner.

When the potential applied to *CR1* swings from its most negative to its least negative value however, *CR1* becomes forward biased, effectively disabling the cross-coupling circuit. Capacitor *C1* then serves as the only cross coupling between the collector of *Q2* and the base of *Q1*, causing the circuit to become a univibrator. Upon the application of a positive trigger pulse to the base of *Q2*, the circuit triggers. After a timed interval, determined by the charging time of *C1*, it is restored to its original condition.

START-STOP OSCILLATOR

The basic timing means, whereby the signal is converted from sequential start-stop to parallel 5-wire form at the transmitter, and conversely at the receiver, is the start-stop oscillator. Each character of the start-stop signal being received by the code converters at the transmitting terminal triggers the start-stop distributor, which then samples the incoming signal. Once started, the start-stop oscillator oscillates through six cycles and comes to rest of its own accord. Fig. 6 shows the oscillator and clamp, together with associated circuitry, in simple block diagram form. The basic oscillator is of the negative resistance type with an inductance/-capacitance (I/C) tank connected in the base circuit of a point-contact transistor. The frequency of oscillation is such that one period is equal in time duration to that of one code pulse in the start-stop signal. For example, at 60 winds per minute the period of oscillation is 22 milliseconds, which corresponds to a frequency of 45.45 cycles per second. The output is applied to the distributor drive circuits in order to step the start-stop distributor. Beginning with the start element, the distributor will cycle through each of its seven elements at the oscillator frequency rate. When next the stop element fires, a signal will be fed to the control circuits which will in turn cause the clamp switch to become effectively a short circuit across the oscillator tank. Oscillations will then be clamped until the next start pulse is received by the control circuits. This oscillator is inherently stable within ±1 per cent over a 0–60-degree-centigrade temperature range.

POWER SUPPLY

The power unit is an unregulated multiple-voltage supply, consisting of a power transformer, germanium full-wave rectifiers, and I/C filtering. The principal operating voltage is −22 volts. This voltage supplies the ring distributors, storage elements, and nearly all other circuits. In addition, a separate variable −22-volt supply has been included in the system as a test facility for voltage margin measurement. It is possible to vary the −22-volt supply in each drawer, without affecting the rest of the equipment, in order to detect marginal circuits.

The equipment is designed for 115-volt 60-cycle operation. However, all circuits will operate with input variations of from 90 to 125 volts, 50 to 60 cycles.

Packaging

Extreme miniaturization was not the primary objective in packaging the equipment, although the transistorized multiplex occupies only approximately 25 per cent of the total volume of the vacuum-tube send-receive set. Reliability and serviceability were considered of primary importance, but consistent with these, miniaturization was to be desired. To this end, half-watt 5-per-cent carbon resistors and metalized paper capacitors with 200-volt d-c ratings were adopted as standard. Transistor sockets were provided for replacement of the transistors as a conservative approach to the mounting problem, even though a high degree of transistor reliability was anticipated. A combination of proved mounting techniques and etched circuit wiring was used. Conventional terminals were employed for securing circuit components, which facilitate replacement of parts in the field. All circuit elements are mounted on etched circuit cards and are spaced conservatively, with adjacent components not mounted closer than 0.3 inch center to center. A typical drawer assembly is shown in Fig. 7.

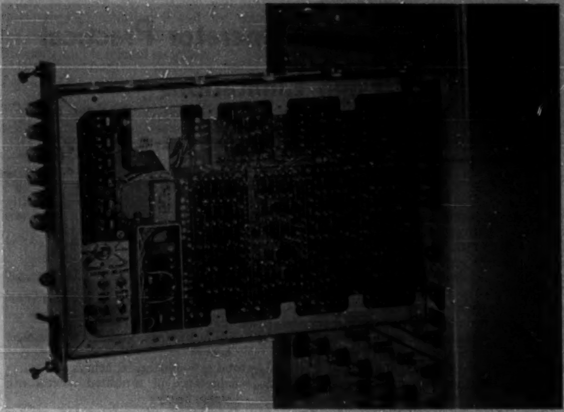

Fig. 7. Transistorized multiplex showing typical drawer assembly

Several circuit cards are mounted on a larger etched wiring panel, and connected to it by wire straps and conventional soldered terminals in order to facilitate removal and replacement of the cards as modular units, without introducing a large number of friction contact connections. The wiring panel thus serves as a chassis and local cable. It is mounted vertically in a drawer assembly, which may be withdrawn from the cabinet as shown in Fig. 7. All components are visible and readily accessible when the individual drawers are withdrawn.

There are 14 drawers in the system, in addition to the power supply. They are comprised of seven basic types, which slide into vertical slots in the send and receive group enclosures. A novel collapsible cable assembly has been provided which allows the drawers to be withdrawn without interrupting traffic while the equipment is operating. Convenient equipment accessibility is thereby achieved without the necessity of connecting adapter cables and plugs.

This method of packaging for convenience of maintenance was adopted as a conservative design approach. In view of the low voltages and operating temperatures throughout the equipment, need for servicing and replacement of components is expected to be infrequent.

The cabinet is of aluminum construction throughout. It is designed to permit removal of the send and receive groups and power supply for external rack mounting if desired. The external cabinet is therefore basically no more than a protective cover for the equipment. All interconnections between local send and receive groups and between drawers are accomplished via cross-connecting panels located at the rear of the group enclosures, and by patch cords between the group enclosures and power supply.

Operation

The transistor multiplex, while still in the developmental stage, has shown promise of providing extremely high reliability in operating service. Transistor and component failures traceable to circuit operation have been almost nonexistent. Some breadboard circuitry has been operating for as long as 2 years without failure. Those few failures which have occurred have been in junction transistor circuits and were traceable either to increased reverse current, or loss in current gain. To date, there have been no operating failures of point-contact transistors. Future field and laboratory tests should provide additional information which will permit more accurate prediction of the ultimate reliability to be expected of the equipment.

Conclusions

Application of solid-state devices to the multiplexing function, enabling the reduction of volume and power requirements, should provide new applications for the transistor multiplex. Decreasing transistor and diode costs indicate that when it is produced in quantity, the transistor multiplex will be competitive in price with the vacuum-tube multiplex. What is most important, however, is that the expected long life of transistors should provide a degree of reliability so far unobtainable in electronic equipment.

Synopsis: Saturable reactors can be used to produce narrow pulses from a periodic supply without the use of electron tubes. An increasingly popular circuit for producing pulses is known as the Melville Line. The original paper[1] describing the circuit is an excellent treatise on the theory of the circuit and includes some practical considerations. Another paper[2] presents a method of determining the number of stages in the circuit for minimum total core volume. There are limitations to the circuit which are determined by core characteristics. Also, by use of the relations developed, a designer can determine whether or not C cores can be substituted for toroidal cores to simplify winding and insulating.

THE MELVILLE LINE pulse generator produces pulses from a periodic supply. For most general applications, a sine-wave supply is selected to describe the circuit operation. However, any periodic wave shape may be used.

The upper power level of the generator is dependent upon the insulation and cooling techniques applied. The lower power level is limited by core characteristics.

The pulse-repetition rate is a multiple of the input frequency. The two basic circuits described here are for single-cycle and bi-cycle operation, and are defined by the number of pulses produced per cycle of the supply.

Nomenclature

A = effective core cross-sectional area, cm² (centimeters)
B_s = flux density at saturation, gausses
C_n = capacitance of nth-stage capacitor, farads
D_n = ratio of pulse width to pulse period for nth stage, duty cycles
e_{c1} = instantaneous voltage across C_1, volts
e_{L1} = instantaneous voltage across L_1, volts
E_0 = peak input voltage, volts
H_c = coercive force, oersteds
I_n = peak current through nth stage, amps (amperes)
I_n' = magnetizing current in nth-stage reactor, amps
J = energy in output pulse, watt-secs (watt-seconds)
l_a = air-gap total length, cm
l_i = total path length of core, cm
l_n = total path length of core in nth stage, cm
L_a = air coil inductance, henrys
L_l = leakage inductance, henrys
L_μ = self-inductance neglecting leakage, henrys
L_t = total self-inductance, henrys
L_{sn} = inductance of saturated reactor nth stage, henrys
$L_{\mu n}$ = inductance of unsaturated reactor nth stage, henrys
N_n = number of turns nth stage
R = resistance of load, ohms
μ_e = effective unsaturated permeability of core assembly
μ_i = effective unsaturated permeability of core material
σ = core volume, cm³
τ_n = half-amplitude pulse width of current in nth stage, secs
τ_R = half-amplitude pulse width of current in final stage, secs
ω_0 = input frequency

Bi-Cycle Operation

The magnetic-pulse generator in its simplest form consists of an L/C (inductance-capacitance) input circuit and an L/R/C (inductance reactance capacitance) saturable reactor circuit shown in Fig. 1. The two circuits share the same capacitor, C_1.

A sine-wave voltage, applied at the input, will produce an alternate-polarity output pulse as shown in Fig. 2. This is called bi-cycle operation, since two output pulses are produced per input cycle.

INPUT CIRCUIT

The input circuit consists of a linear L/C series circuit, resonant with the input frequency. If the circuit is connected to a sine-wave input supply at the time the line voltage is passing through zero, the voltage across the capacitor will follow the wave shape e_{c1}, as shown in Fig. 3. The equation of the voltage across capacitor C_1 for the lossless case is as follows:

$$e_{c_1}=\frac{E_0}{2}(\sin \omega_0 t-\omega_0 t\cos \omega_0 t) \tag{1}$$

A voltage peak will appear across C_1 at time: π/ω_0, $2\pi/\omega_0$, $3\pi/\omega_0$, $4\pi/\omega_0$, etc.

If allowed to continue, the peak capacitor voltage will approach a limit of Q times the applied voltage peak E_0. In bi-cycle operation, the wave shape e_{c1} is interrupted at π/ω_0 by the saturable-reactor circuit the explanation of which follows.

SATURABLE REACTOR CIRCUIT

The saturable-reactor circuit consists of an L-R-C series circuit in which L_1 is a saturable reactor. The unsaturated inductance of the saturable reactor is shown as L_{u1} in Fig. 4, and the saturated inductance as L_{s1}. The closing of switch SW symbolizes the saturation of the saturable reactor L_1.

The unsaturated reactance of L_1 is required to be much greater than the reactance of C_1.

$$\omega_0 L_{u1} >> \frac{1}{\omega_0 C_1} \tag{2}$$

The symbol >> in this paper indicates "is greater than 20." If the condition of equation 2 is fulfilled, the voltage across L_1 is approximately equal to the voltage of capacitor C_1.

$$e_{L1}\approx e_{c1} \tag{3}$$

The flux density of L_1 can be determined by the integral form of Faraday's Law

$$B=-\frac{10^8}{NA}\int e_{L1}dt \tag{4}$$

For bi-cycle operation, L_1 is required to saturate twice per cycle. At the time of saturation, the core flux density of L_1 equals B_s. During the interval 0 to π/ω_0 the total change in flux density is $2B_s$ as shown in Fig. 5. When equations 1 and 3 are used with equation 4

$$2B_s=-\frac{10^8}{NA}\int_0^{\pi/\omega_0}\frac{E_0}{2}(\sin \omega_0 t-\omega_0 t\cos \omega_0 t)dt$$

$$|B_s|=\frac{E_0 10^8}{\omega_0 NA} \tag{5}$$

The voltage, flux density, and hysteresis loop of L_1 are plotted in Fig. 5.

When L_1 saturates at π/ω_0, its inductance changes abruptly from L_{u1} to L_{s1} as represented by the switch SW closing in Fig. 6.

The series circuit consisting of C_1, L_{s1}, and R is designed for critical damping.

The current through the critically damped circuit follows the relation

$$i=\frac{E_0\pi t}{2L_{s1}}\epsilon^{-\frac{t}{\sqrt{L_{s11}C}}} \tag{6}$$

The current has a peak amplitude at $t=\sqrt{L_{s1}C_1}$, and reaches half peak amplitude at $t=0.23\sqrt{L_{s1}C_1}$ and $2.69\sqrt{L_{s1}C_1}$.

Paper 56-728, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 28, 1956; made available for printing April 30, 1956.

M. F. THOMPSON, R. R. TRAUTWEIN, and E. R. INGERSOLL are with Autonetics, a division of North American Aviation, Inc., Bellflower, Calif.

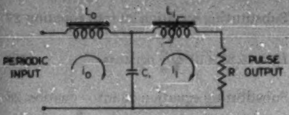

Fig. 1. Basic circuit bi-cycle operation

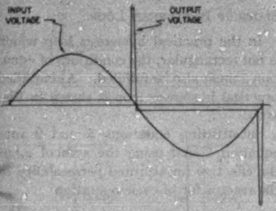

Fig. 2. Bi-cycle operation

Therefore the half-peak-amplitude width of the current pulse is

$$\tau_H = 2.69\sqrt{L_{s1}C_1} - 0.23\sqrt{L_{s1}C_1} \qquad (7)$$

or

$$\tau_H = 2.46\sqrt{L_{s1}C_1} \qquad (8)$$

The output pulse width will be arbitrarily assigned as the half-amplitude width given in equation 8.

REACTOR SELF-INDUCTANCE

The self-inductance of a reactor with a fully saturated iron core or an air coil depends only on the configuration of the coil. Let this inductance equal L_a.

The self-inductance of a reactor with a very-high-permeability core is given by the following relation:

$$L_\mu = \frac{0.4\pi N^2 \mu_e A 10^{-8}}{l_i} \qquad (9)$$

As the core saturates and μ_e approaches that of the surrounding medium (1 for air), some flux lines do not link all the turns of the coil. When the core is fully saturated, equation 9 will not yield the exact inductance unless:

1. The cross-sectional area of the core and coil are equal.
2. The winding is evenly distributed along the core.
3. The core-path length is much greater than the build-up or strip width of the core.

These three conditions cannot be fulfilled in practical reactor design, since they result in:

1. No space for insulation between core and coil.
2. Large outside dimensions of the core, even for a small cross-sectional area.

The difference between the iron-core inductance of equation 9 and the total self-inductance is called the leakage inductance and is related as follows:

$$L_t = L_\mu + L_l \qquad (10)$$

When the core is fully saturated, the total self-inductance equals the air inductance:

$$L_s = L_a = L_\mu + L_l \qquad (11)$$

Substituting equation 9 into equation 11, with a permeability of 1

$$L_l = L_a - \frac{0.4\pi N^2 A 10^{-8}}{l_i} \qquad (12)$$

Relations for L_a are available in tables for many types of configurations. Substituting equation 12 into equation 11 for permeability equal to μ

$$L_t = (\mu_e - 1)\frac{0.4\pi N^2 A 10^{-8}}{l_i} + L_a \text{ (henrys)} \qquad (13)$$

The curves of these parameters are plotted in Fig. 7.

DUTY CYCLE OF BASIC CIRCUIT

The following development is based on an ideal saturable reactor with a hysteresis loop shown in Fig. 8(A). This hysteresis loop has no coercive force, and infinite unsaturated permeability. The leakage inductance of the saturable reactor is assumed to be zero.

A measure of the ability of the pulse generator to form narrow pulses can be expressed by the duty cycle D.

$$D = \frac{\text{pulse width}}{\text{pulse period}} \qquad (14)$$

For bi-cycle operation

$$\text{pulse period} = \frac{\pi}{\omega_0} \qquad (15)$$

Substituting equations 8 and 15 into equation 14

$$D = \frac{\omega_0}{\pi} 2.46\sqrt{L_{s1}C_1} \qquad (16)$$

Since the leakage inductance is zero

$$L_l = 0 \qquad (17)$$

From equation 12

$$L_{s1} = L_a \approx \frac{0.4\pi N^2 A 10^{-8}}{l_i} \qquad (18)$$

Substituting equation 5 into equation 18

$$L_{s1} = \frac{0.4\pi}{Al}\left(\frac{E_0}{B_s\omega_0}\right)^2 10^8 \qquad (19)$$

Let

$$Al = \sigma \qquad (20)$$

Substituting equations 19 and 20 into equation 16

$$D = \frac{2.46 E_0 10^4}{\pi B_s}\sqrt{\frac{0.4\pi C_1}{\sigma}} \qquad (21)$$

The total energy in each pulse is as follows

$$J = \frac{C_1 E_0^2 \pi^2}{8} \text{ watt-secs} \qquad (22)$$

Substituting equation 22 into equation 21

Fig. 4. Equivalent circuit bi-cycle operation

$$D=\frac{7.93\times10^{3}}{B_s}\sqrt{\frac{J}{\sigma}} \tag{23}$$

Equation 23 shows that the output pulse width may be decreased by increasing the saturation flux density of the core material or the volume of core material. The pulse may also be narrowed by decreasing the energy content of the pulse, but this is usually a fixed design requirement that cannot be altered.

WIDTH OF HYSTERESIS LOOP

Design restrictions in a basic circuit, caused by the width of the hysteresis loop, are described in this section, and those caused by the slope of the hysteresis loop in the following section.

If a rectangular hysteresis loop is considered with a coercive force H_c and saturation flux density B_s as shown in Fig. 8(B) the magnetizing current equals

$$I'=\frac{H_c l}{0.4\pi N}\text{ amps} \tag{24}$$

For obtaining a pulse output, the peak current I must be greater than the magnetizing current, or

$$I>>I' \tag{25}$$

For critical damping and bi-cycle operation

$$I=\frac{\pi E_0}{2\epsilon}\sqrt{\frac{C_1}{L_{s1}}}\text{ amps} \tag{26}$$

Again, when the ideal reactor is considered, with no leakage inductance but with a rectangular hysteresis loop, and equation 18 is substituted into equation 26, and equations 24 and 26 into equation 25

$$H_c<<\frac{\pi E_0 10^4}{2\epsilon}\sqrt{\frac{C_1 0.4\pi}{\sigma}}\text{ oersteds} \tag{27}$$

Substituting equation 22 into equation 27

$$H_c<<5.83\times10^{3}\sqrt{\frac{J}{\sigma}}\text{ oersteds} \tag{28}$$

Substituting equation 23 into equation 28

$$D>>1.36\,\frac{H_c}{B_s}\text{ oersteds} \tag{29}$$

SLOPE OF HYSTERESIS LOOP

In the practical hysteresis loop which is not rectangular, the conditions of equation 2 must also be fulfilled. A simplified practical hysteresis loop is shown in Fig. 8(C).

Substituting equations 5 and 9 into equation 2 and using the symbol μ_e as the effective unsaturated permeability of the reactor for bi-cycle operation

$$\mu_e>>\frac{B_s^2\sigma10^{-8}}{E_0^2C_1 0.4\pi} \tag{30}$$

Substituting equation 22 into equation 30

$$\mu_e>>9.82\times10^{-9}\,\frac{B_s^2\sigma}{J} \tag{31}$$

Substituting equation 23 into equation 31

$$D^2>>\frac{0.617}{\mu_e} \tag{32}$$

Equation 32 shows that the ultimate pulse sharpening ability is limited by the unsaturated permeability. Equation 23

"C" Core Considerations

Uncut toroidal cores with grain-oriented 50-per-cent nickel-iron material approach the rectangular hysteresis loop more closely than cut cores or silicon-iron cores. However, there are production disadvantages to the uncut toroid design that can be simplified by cut *C* cores or by stacked laminations. The stacked laminations and *C* cores permit winding of the coils separately and addition of the cores later. This advantage is particularly evident in the high-power pulse generator where high voltages are encountered, and where many turns are required in the earlier stages.

Stacked laminations have good electrical properties because of a small air gap, but cut *C* cores afford a minimum assembly time.

The rectangular hysteresis-loop characteristics of highly grain-oriented nickel-iron core material are impaired when assembled as stacked laminations or cut *C* cores. This is caused by the strain-sensitive nature of the highly grain-oriented material. However, where strain is encountered silicon-iron grain-oriented core material can be used during assembly without damaging the characteristics.

Although the Hipersil hysteresis loop is not rectangular, equation 31 states that for high pulse energies the lack of rectangularity may be permitted.

Equation 33 is a convenient arrangement of requirements to decide whether or not *C* cores may be used in place of toroids. However, these equations are only approximate, since they do not include the leakage inductance.

The effect of the air gap must also be considered. A well-known expression relates the effective core permeability μ_e and the iron permeability μ_i with the total length of the air gap l_a and the iron path length l_i.

$$\mu_e=\frac{\mu_i}{\left(\mu_i\frac{l_a}{l_i}+1\right)} \tag{34}$$

During the unsaturated period of the saturable reactor, the permeability of the core can be in the category of 100,000. If the core path length is 10 inches and the air gap is 1/10 mil

$$\mu_e=\frac{100{,}000}{\left(100{,}000\frac{0.0001}{10}+1\right)}=50{,}000$$

Thus, even a 1/10-mil air gap can seriously influence the unsaturated permeability.

Single-Cycle Operation

The bi-cycle circuit shown in Fig. 1 may be changed to single-cycle operation by applying a bias current through a bias winding and choke as shown in Fig. 9. Single-cycle operation produces unipolarity pulses at a repetition rate of 1 per cycle of the input supply. The output pulses are shown in Fig. 10 with the positive and negative voltage time area denoted by A_P and A_N respectively. Although the pulses are unipolarity, no d-c output is produced, since the positive and negative areas are equal.

Input Circuit

The single-cycle and bi-cycle input circuits are similar. Each consists of a linear L/C series circuit, resonant with the input frequency. In single-cycle operation, the wave form e_{c1} is interrupted at $2\pi/\omega_0$ by the saturable-reactor circuit, the explanation of which follows.

Saturable-Reactor Circuit

The saturable-reactor circuit of single-cycle operation is similar to bi-cycle operation, except for the bias circuit which polarizes the saturable reactor to permit saturation in one direction only. The solid lines in Fig. 11 show the hysteresis loop for single-cycle operation.

As the voltage, shown in Fig. 12(A), is applied to L_1, its core flux density follows the wave form shown in Fig. 12(B), according to Faraday's law, equation 4.

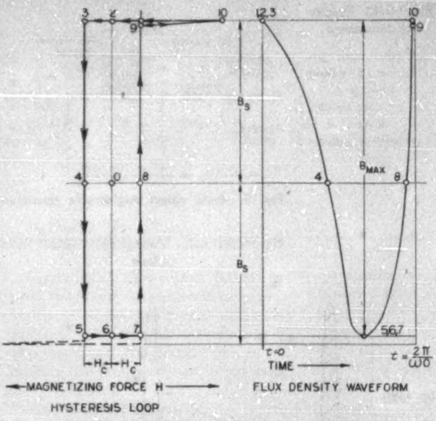

Fig. 11. First-stage hysteresis-loop single-cycle operation

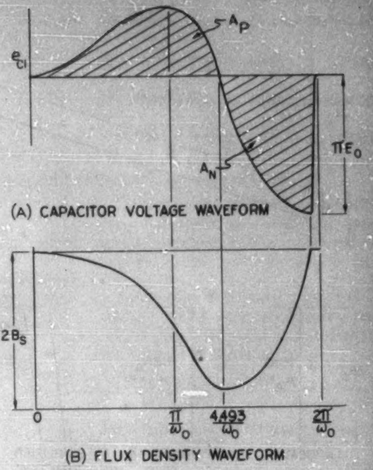
Fig. 12 (right). First-stage flux-density single-cycle operation



At time $2\pi/\omega_0$ the reactor saturates and the capacitor discharges through L_1 and R. This capacitor discharge is shown in Fig. 12(A) in the vicinity of time $2\pi/\omega_0$. A finite discharge time is required, but for simplicity equation 36 assumes a zero discharge time. With this modification, the voltage wave form crosses the zero voltage axis at time $4.493/\omega_0$ and $2\pi/\omega_0$. Since the positive and negative voltage time areas are equal, the integral limits in equation 35 may be either 0 to $4.493/\omega_0$ or $4.493/\omega_0$ to $2\pi/\omega_0$. Either set of limits will give the same maximum flux density. This flux density wave form is repeated again in Fig. 11 to show its relation to the hysteresis loop.

Applying equation 4

$$2B_s = -\frac{10^8}{NA}\int_0^{4.493/\omega_0}\frac{E_0}{2}(\sin\omega_0 t - \omega_0 t\cos\omega_0 t)dt \qquad (35)$$

$$B_s = \frac{1.7E_0}{\omega_0 NA}10^8 \qquad (36)$$

Following the same manipulation as was employed under the headings "Duty Cycle of Basic Circuit," "Width of Hysteresis Loop," and "Slope of Hysteresis Loop"

$$D = \frac{3.36\times10^3}{B_s}\sqrt{\frac{J}{\sigma}}$$

$$D >> 0.574\frac{H_c}{B_s}$$

$$D^2 >> \frac{0.154}{\mu_e} \qquad (37)$$

Additional Stages

The ultimate pulse-sharpening ability of a one-stage magnetic-pulse generator is limited by the relations shown in equation 33 for bi-cycle operation, and in equation 37 for single-cycle operation. If sharpening is required beyond the limitations of these equations, additional stages must be added to the circuit.

Additional inserted stages are shown in Fig. 13. This circuit has been chosen for bi-cycle operation, to illustrate how stages are added. A bias could be added to L_1 as in Fig. 9, if single-cycle operation is desired.

All additional stages are L/C-series circuits, sharing capacitors with adjacent stages. The stage immediately following the input stage is defined as the first stage. Stages beyond the first stage are intermediate stages. The stage including the load is called the final stage. The first stage and intermediate stages are identical in operation during their saturated period, but during their unsaturated period the wave forms of the two types differ.

In all the following equations, all capacitors will be equal or

$$C_1 = C_2 = C_3 = C_n = C \qquad (38)$$

FIRST STAGE

The first stage circuit consists of C_1 and C_2 in series with L_1 as shown in Fig. 13.

For bi-cycle operation, equations 2 through 6 apply directly, while L_1 is unsaturated. However, when L_1 is saturated, the circuit becomes an L/C/C (inductance capacitance capacitance) instead of an L/R/C circuit, and equations 7 and 8 do not apply. The wave forms for the first stage circuit, while L_1 is saturated, are shown in Fig. 14

At time π/ω_1 the charge on C_1 has been completely transferred to C_2. For the linear, lossless case, the circuit would oscillate indefinitely. However, L_2 saturates at π/ω_1 and C_2 is discharged through the second stage. The discharge time of C_2 is much less than π/ω_1 as shown in Fig. 14.

Fig. 14. Operation after saturation; first and intermediate stages

The half-amplitude width of the first stage current pulse equals

$$\tau_1 = \frac{\pi}{3}\sqrt{2L_{s1}C} \tag{39}$$

A procedure similar to that described in the afore-mentioned three sections can be used to determine the first-stage duty-cycle restrictions for bi-cycle operation.

$$D_1 = \frac{4.76\times 10^3}{B_{s1}}\sqrt{\frac{J}{\sigma_1}}$$

$$D_1 >> 0.425\frac{H_{c1}}{B_{s1}}$$

$$D_1^2 >> \frac{0.222}{\mu_{s1}} \tag{40}$$

For single-cycle operation, the first-stage duty cycle restrictions are as follows:

$$D_1 = \frac{2.03\times 10^3}{B_{s1}}\sqrt{\frac{J}{\sigma_1}}$$

$$D_1 >> 0.180\frac{H_{c1}}{B_{s1}}$$

$$D_1^2 >> \frac{0.0555}{\mu_{s1}} \tag{41}$$

INTERMEDIATE STAGE

The intermediate-stage circuit is identical to the first-stage circuit. However, the voltage applied to the intermediate-stage saturable reactor before saturation is sinusoidal.

For bi-cycle operation

$$e_{Ln} = \frac{E_0\pi}{2}\sin\omega_{n-1}t \tag{42}$$

$$\omega_{n-1}L\mu_n >> \frac{1}{\omega_{n-1}C} \tag{43}$$

By using equations 42 and 43 in a procedure similar to those already described, the intermediate-stage duty-cycle restrictions for bi-cycle operation can be found

$$D_n = \frac{5.89\times 10^3\omega_0}{B_{s_n}\omega_{n-1}}\sqrt{\frac{J}{\sigma_n}}$$

$$D_n >> \frac{0.524\omega_0 H_{c_n}}{B_{s_n}\omega_{n-1}}$$

$$D_n^2 >> \frac{0.222}{\mu_{s_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)^2 \tag{44}$$

For single-cycle operation, the intermediate-stage duty-cycle restrictions are as follows:

$$D_n = \frac{2.95\times 10^3}{B_{s_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)\sqrt{\frac{J}{\sigma_n}}$$

$$D_n >> \frac{0.262H_{c_n}}{B_{s_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)^2$$

$$D_n^2 >> \frac{0.0555}{\mu_{s_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)^2 \tag{45}$$

FINAL STAGE

The final-stage and intermediate-stage wave shapes are identical before saturation.

Therefore, for bi-cycle operation, equations 42 and 43 apply directly. However, after saturation, the final stage circuit becomes a critical damped L/R/C circuit, and the half-amplitude width of the current pulse equals

$$\tau_n = 2.46\sqrt{L_{s_n}C} \qquad (46)$$

Again, applying a similar procedure the final-stage duty-cycle restrictions for bi-cycle operation are determined.

$$D_n = \frac{9.79\times10^3}{B_{s_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)\sqrt{\frac{J}{\sigma_n}}$$

$$D_n >> \frac{1.68H_{c_n}}{B_{s_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)$$

$$D_n^2 >> \frac{0.617}{\mu_{e_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)^2 \qquad (47)$$

For single-cycle operation, the final-stage duty-cycle restrictions are

$$D_n = \frac{4.88\times10^3}{B_{s_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)\sqrt{\frac{J}{\sigma_n}}$$

$$D_n >> \frac{0.836H_{c_n}}{B_{s_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)$$

$$D_n^2 >> \frac{0.154}{\mu_{e_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)^2 \qquad (48)$$

Combined Wave Forms

The combined wave forms of a 2-stage single-cycle pulse generator are shown in Fig. 15. In actual circuits, the time period $\pi/\omega_1 << 2\pi/\omega_0$ and the output pulse width is much less than π/ω_1. For simplicity, the intermediate stages have been omitted. The time scale has been distorted to show the wave shape of narrow pulses which are actually very narrow compared to the input period.

It should be noted that the total wave shape must be completed in a $2\pi/\omega_0$ time interval to satisfy the stability requirement that the input wave shape must be shortened to allow for all stages to complete the cycle in a total period of $2\pi/\omega_0$. Consequently, the input capacitor charge time is less than π/ω_0 for bi-cycle firing, and less than $2\pi/\omega_0$ for single-cycle firing.

Magnetron Load

The pulse generator circuit is in common usage to drive a high-power magnetron.

A typical magnetron has an input voltage-current characteristic which approximates a biased diode, as shown in Fig. 16. As a result of biased diode action, the final-stage output voltage is clipped by the magnetron. This clipping action has a tendency to square the magnetron output pulse.

Design Procedure

A magnetic-pulse generator may be designed to meet one or more of the following design goals in accordance with its particular application:

1. Minimum core volume.
2. Maximum efficiency.
3. Minimum weight.
4. Minimum size.
5. Minimum number of stages.
6. Maximum ease of production.

This paper will not discuss methods of obtaining a design goal. However, for a given design, this paper provides a means of checking each stage for adequate shape of the hysteresis loop. The requirements are summarized in the following form

$$D_n^2 >> \frac{K_u}{\mu_{e_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)^2 \qquad (49)$$

$$D_n >> K_H\left(\frac{\omega_0}{\omega_{n-1}}\right)\left(\frac{H_{c_n}}{B_{s_n}}\right) \qquad (30)$$

$$D_n = \frac{K_J10^3}{B_{s_n}}\left(\frac{\omega_0}{\omega_{n-1}}\right)\sqrt{\frac{J}{\sigma_n}} \qquad (51)$$

The following table applies to bi-cycle operation and single-cycle operation:

Symbol	One-Stage Generator	First Stage	Intermediate Stages	Final Stage
Bi-Cycle Operation				
K_u	0.617	0.222	0.222	0.617

The Technical Feasibility of Translating Languages by Machine

VICTOR H. YNGVE
NONMEMBER AIEE

RECENT DEVELOPMENTS in the design of electronic digital computers have suggested the possibility of translating languages by machine, but when one tries to write a good translation program for a computer, one finds that there is much to be learned about language. For this reason, no program has yet been written by which a computer could translate usefully; but a number of people have been challenged by the problem of filling in the gaps in present knowledge about language and translation.[1,2]

This increasing interest in the possibility of mechanical translation is not surprising. Translation on a large scale is becoming more and more urgent in a rapidly shrinking world still partitioned by many language barriers. There are at least 50 languages that possess written records worth translating, and at least 200 languages into which the scientific, technical, and cultural records of our civilization might be translated. The price that each language community pays for the luxury of expressing itself in its own language is the cost and the difficulty of communication with the rest of the world. Today, communication between language communities must be funneled through individuals who are to some extent bilingual. If special-purpose machines could be devised for translating written material, the cost of translation would be significantly reduced. Language communities could then retain their individuality and still gain the advantages of increased communication.

This paper will explore two types of mechanical translation. The first, which can be called word-for-word translation, is within immediate reach, but promises results that are crude, at best. The second type, sentence-for-sentence translation, which is the type being studied at the Research Laboratory of Electronics, Massachussets Institute of Technology, promises translation of a higher quality, but a great deal of effort will be required to work out the linguistic details.

Word-for-Word Translation

Word-for-word translation is based on the use of a dictionary. The words of the input text are looked up in order, one by one, in a dictionary, and the meanings are written down in order, one by one. In determining the meanings, only one text word at a time is considered.

Word-for-word translations can be produced by machine in the following way: The material to be translated is typed on a keyboard device which transfers the characters to some input medium such as punched tape, punched cards, or magnetic tape for entry into the machine. The machine then compares the words one at a time with the dictionary entries that are stored in the memory. When each input word is located in the memory, the dictionary entry stored there provides a meaning that consists of an equivalent word or words in the other language. The equivalents found in the dictionary are then sent one at a time to an output printer that prints a word-for-word translation.

If a machine that can produce rough translations on a production basis is wanted as soon as possible, the word-for-word machine is the favored type because it is simple and can be implemented now. If translations better than word-for-word translations are wanted, work on an automatic dictionary should still be undertaken because any machine that translates will need a dictionary, and the technical problems arising in the design of an automatic dictionary are not trivial.

There are good reasons for taking the word, delimited by spaces or punctuation, as the item to be looked up, instead of some smaller unit. It has been suggested that if the roots of words and their inflectional endings were stored in the memory separately, much space would be saved in the dictionary. If a given word can be inflected in five ways, the number of entries in the dictionary could, perhaps, be reduced by nearly four-fifths, since the inflectional endings are common to many words. As another space-saving device, it has been suggested that compound words, such as *blackboard, counterelectromotive, Koordinatenanfangspunkt*, could be separated into their component parts, and each part looked up separately. Suggestions such as these for splitting up words have at least two disadvantages. One is that the separation of a word into parts before it is looked up requires a method for deciding where to make the separation. Part of the storage space saved has to be used for a more complicated program or look-up routine. Another disadvantage is that parts of words and inflectional endings have, in general, more different meanings than fully inflected words. Strict word-for-word translation completely avoids the segmentation problems and avoids some of the multiple meanings of parts of words—inflectional endings, in particular.

In the next sections, word-for-word translation will be considered in detail. The requirements of the task will be compared with the capabilities of present-day, general-purpose digital computers and of special-purpose machines that might be constructed for translation; then the usefulness of the product will be assessed.

MACHINE REQUIREMENTS: SIZE

The size of the memory of a machine is of importance in word-for-word translations. Memory size depends upon the number of dictionary entries, the average length of each entry, and, in stored-program machines, on the storage requirements of the program.

The number of words in a language is difficult to estimate. If the entries in dictionaries are counted, numbers around a million are obtained. However, no dictionary contains all the words of a language; new words are being added every day. The vocabulary of a language is not a closed system; it is always open to additions. If translating is limited to one field of knowledge (electrical engineering, for example) most of the words belonging to other fields may never appear, and a glossary containing electrical engineering terms and certain general scientific terms might be adequate. But, like the vocabulary of an entire language, the vocabulary of a specific field is not closed; and an author of a paper in a special field often uses terms from other fields.

A glossary should contain the words most frequently used in a specific field. Since it is virtually impossible to list all the words of a language, or even of a specific field, new words will have to be added from time to time as they are needed. It is feasible to start with a rather small list of words and add new ones where they are first encountered or after they have appeared a given number of times. In this way, the glossary is always an approximation to a list of the words of highest frequency in the specific field.

The most important parameter to be considered in evaluating a glossary is not the number of words that it contains, but some parameter connected with the number of running words of a text that can be found in the glossary. The coverage of a glossary with respect to a certain test can be defined as the ratio of the number of running words of the text that can be found in the glossary to one more than the number of words that cannot be found. It is the average length of uninterrupted runs of text words that can be found in the glossary. The coverage of an English glossary with respect to a Russian article is zero. The coverage of a glossary containing the 50 or 60 most frequently used English words is about one, because these words make up about half of the running words in a text. The coverage of a glossary with respect to an article is numerically equal to the number of words in the article if the glossary contains them all. To have a reasonably high coverage with respect to a field such as electrical engineering, a glossary should contain at least 5,000 carefully chosen words.

In assessing the size of memory needed for an automatic dictionary, it is also important to form some estimate of the length of each entry. The distribution of lengths of the different words in a language is characteristic of the language. In English, the average word length is about 7 or 8 letters; in German it is somewhat longer. German has many words with more than 20 letters. Since word lengths are so variable, and since each entry may contain one or more words as equivalents, there will be considerable variation in entry size. Perhaps the average size will be something like 20 letters; the maximum size may run to more than 100.

The amount of storage needed for a minimum dictionary of 5,000 entries with an average entry size of 20 characters of

5 binary digits each is 500,000 binary digits.

Now that an estimate of the memory capacity requirements has been made, the adequacy of present-day machines can be examined. Many general-purpose digital computers have three kinds of memory: magnetic core, magnetic drum, and magnetic tape. A storage capacity of 500,000 binary digits is, by present standards, large for a magnetic core memory. Even many magnetic drum machines do not have this capacity. One is forced to the conclusion that magnetic-tape storage must be used with most present-day general-purpose computers if an adequate dictionary is to be stored.

MACHINE REQUIREMENTS: SPEED AND ECONOMY

While the ability of a machine to make word-for-word translations is determined primarily by the size of the glossary that it can store, its usefulness for producing translations economically depends on a number of factors. These include the cost of operating the machine, the access time of the memory, the register length, the type of commands available and their execution times, and the way in which the program is written.

In present-day machines the memories are organized by address. This means that the memory contains a number of pigeon holes or memory locations, each one designated by a number. The machine is arranged so that ready access is obtained to each memory location when it is referred to by its address. The average time that it takes to refer to a given address and extract the contents of the memory from that position is called the access time. For core memories the access times are very short, in the neighborhood of 10 to 20 microseconds. For drum and tape memories, the concept of access time is not quite as appropriate, since the actual time required to find something at a given address varies greatly, being dependent on the time it takes the drum or tape to move to that address. Average access times for drums are around 10 milliseconds.

In a dictionary look-up program, the access time is not the only factor in determining how quickly a given word can be found; although the word is known, its address is not. The binary representation of the word itself cannot be used as the address, because the spelling of words is highly redundant. For a 5,000-word memory, the address would need to be only 13 binary digits long; but the spelling of a word might require well over 100 binary digits.

Various programming methods have been devised for searching a memory when the address is unknown. Clearly, it is not economical of time to start at the beginning and examine each entry in turn, through the whole dictionary, until the right entry is found. An improvement consists of using the thumb index device, whereby the search is divided into two steps. The initial one or two letters of the word are found in the index part of the dictionary. The index entry gives the position in the main list at which the search should begin. It is possible to extend the thumb index idea and divide the search into three or more steps. If this procedure is carried to the extreme, the bifurcation, or "20-questions," technique is reached. Each step of the search chooses one out of two approximately equal sections of the dictionary. If the division is exactly into two each time, one out of 2^n entries can be found in n trials. Another possibility is to try to obtain from the spelling of the word some function that specifies, as closely as possible, the address of the word. With this scheme, surprisingly good results can be obtained.

It is also possible to take advantage of the vocabulary statistics. The probability p_r that the rth word from the vocabulary will appear next in a text is given by the Zipf law[3] as $p_r = P\,r^{-1}$, where r is the rank of the word when words are ranked in order of decreasing frequency, and P is a constant with a value of approximately 1/10. A more accurate law has been derived by Mandelbrot.[4] It is $p_r = P\,(r+m)^{-B}$, where B is a constant in the neighborhood of one, and m is another constant. The constants P, m, and B are characteristic of different languages and, to some extent, of different authors and styles of discourse. According to these two laws, as few as 50 or 60 different words make up about half of the total words in a text. If these 50 or 60 words are placed in a core memory with effectively instantaneous access, the over-all access time can be reduced by a factor of 2.

For a memory such as magnetic tape, the access time to a given entry depends on its position along the tape in relation to the reading heads. The most effective way to use a magnetic-tape memory is to look up the words in batches, not one at a time. Each batch of words is alphabetized in the fast memory of the machine. All of the words in a batch can be looked up in one pass of the tape, if the words on the tape are also alphabetized. The average rate of access can be greatly increased by this method at the expense of some delay in translation and some storage and manipulation requirements in a fast memory. The concept of random access time is almost meaningless when words are looked up in batches. The appropriate parameters of the system are the average rate of information flow through the machine, and the average delay.

Present-day digital computers have been designed to handle arithmetic at very fast rates. A dictionary search program for one of these machines usually involves a great deal of arithmetic, not because it is required by the problem but because the machine does it so well. A modern fast computer would not be as economical as a machine specifically designed for translation. Such a machine should be capable of handling entries of variable length and designed specifically for searching the memory when the address is not known. It should be specially designed for matching sequences of binary digits, and determining whether the numerical value of one sequence is greater or less than that of another.

Memory research is progressing rapidly. In another few years, high-capacity magnetic-disk memories, special magnetic tape or drum arrangements, or various types of photographic memories will probably be developed to the point where they will be available for translating machines. It may not be necessary to resort to word-splitting techniques in order to store a high-coverage glossary in a machine that is economical to use.

The simple word-for-word translation schemes that have been discussed have the advantage that they can be implemented now. To decide whether or not their implementation is worth while, the potential usefulness of the translations should be considered.

USEFULNESS OF OUTPUT

If translation, from German to English, for example, is considered as the selection of one out of all possible sequences of English words for each German sentence, a word-for-word translation is a good first approximation. English sentences average about 20 words. Assuming a vocabulary of 10^5 words, there are 10^{100} possible sequences of this length. A word-for-word translation may supply an average of about two meanings for each German word. If the word-for-word translation is good, the correct English translation can be found by choosing the correct meaning for each word from those supplied, and then choosing the correct word order. The initial choice of one out of 10^{100} possible sequences has been

Vol.
Pt. 1
1956

reduced to one out of $2^{30} \times 201$, or about one out of 10^{34}. For each sequence left to choose from, approximately 10^{66} have been ruled out. It is thus seen that the word-for-word translation has done a Herculean job, but there is still much work for the reader before he can read the translation. He must still choose one out of 10^{34} possibilities. This he presumably does on the basis of his knowledge of English sentence structure and on the basis of his knowledge of the subject matter. The problems of multiple meaning and of word order are the two difficulties that he must face.

To make the reader's task easier, various suggestions have been made for the arrangement of the multiple choices on the page. They could be strung out in linear order, perhaps with parentheses; or the most likely meaning for each word could be put first or written in bold type; or the various meanings could be listed in columns. Another question concerns the number of meanings that should be provided for each word. Perhaps one broad meaning would be less confusing than two or three narrower meanings. Another suggestion for making the reader's task easier is called partial translation. Partial translation is based on the fact that only a few hundred articles, prepositions, conjunctions, and adverbs make up a large majority of the running words in a text and that these words, together with a few inflectional endings, have especially long multiple-meaning lists. The suggestion is that these few hundred items be given in their original language, not to confuse the reader with long lists. The reader, after a brief introduction to the grammar and sentence structure of the foreign language, would be able to understand these words and endings and the constructions in which they are used. All of the technical terminology would be translated for him.

The reader of the translation plays a vital role. In a sense it is he who makes the translation, because he alone understands the meaning. The machine only recodes the foreign language so that it can be more easily translated by the reader. Experiments have shown that word-for-word translations can be deciphered more easily if the reader is familiar with the topic that is being discussed. If he knows what the author is trying to say, he can recreate the work with very few clues. Thus, word-for-word translation could be useful for people who want to keep abreast of large amounts of foreign technical literature in their field, but it would probably not be adequate for a careful reading of any one article.

It has been suggested that rough word-for-word translations should be revised and edited by an expert. For certain purposes, revision may be advisable, but perhaps the best course would be to let the final reader make his own revision, since he is an expert in the field and can use his background knowledge in deciding what the author probably meant.

It is very important that the final reader be considered a link in the translation chain. Any improvement in the translation which speeds up the reader's comprehension is worth while, since the reader's time is expensive.

CONCLUSIONS

Word-for-word translation can be implemented now by using present-day general-purpose digital computers or, more economically, special-purpose machines. The output might be useful, but would definitely be of poor quality, probably so poor that the reader would have to be highly motivated before he would want to use it.

Sentence-for-Sentence Translation

Attention will now be given to the question: How can a machine produce something better than a word-for-word translation? The deficiencies of word-for-word translations will be examined, not from the point of view of how a reader may cope with them, but from the point of view of how a machine may do so. A diagnosis of the difficulties will be attempted, and a remedy will be proposed. This will necessitate some examination of the way in which words are combined to make sentences in a language.

ANALYSIS OF DIFFICULTIES

The major shortcomings of word-for-word translations have been grouped under multiple-meaning difficulties and word-order difficulties. It is now advantageous to reclassify them as lexical difficulties and structural difficulties.

Lexical difficulties include the multiple meanings of words like *power*, *force*, *integrate*, *potential*, and so on. It has been suggested that the use of a field glossary would restrict these words to one meaning, the technical one. A startling exception to the observation that most nouns, verbs, and adjectives have few meanings is the word *run* which, according to Webster, has 54. (The average number of meanings per word in *Webster's Collegiate Dictionary* is about 2.5.)

Structural difficulties include word order, inflectional endings, multiple meanings of most articles, prepositions, conjunctions, and adverbs. Most of the multiple-meaning difficulties in a text are structural because a majority of the running words in a text are structural words, with more than the average number of meanings. The 54 meanings of *run* are divided into four lists that are structurally different: transitive verb, intransitive verb, noun, and adjective. It is clear that a machine method of handling structural problems is highly desirable.

Diagnosis of the difficulties is easy. After all, a word is usually not ambiguous when its context is considered. In word-for-word translation, no attempt is made to translate a word in its context, but a meaning or meanings are assigned to it on the basis of its form alone. From this point of view, a word-for-word translation might be called a literal translation, whereas a translation which takes into account the context might be called a free translation. Whether a translation is literal or free really depends upon the point of view. A word-for-word translation translates words literally, but translates letters and syllables freely. Words may be translated freely if larger blocks are translated literally. In general, a literal translation will be better if it is based on larger blocks of text.

A way is needed to use the context in translating the words. Investigation has shown that using the context of a complete sentence is a great deal better than using smaller parts of a sentence, say a phrase, but is not significantly worse than using the context of two or more sentences. A sentence seems to be a natural language unit. To see how the information in a sentence context can be used for translation, more knowledge of language structure is needed.

STRUCTURE OF LANGUAGE

The most significant thing which may be said about a sentence is that it has a structure. Some hint of this is given in the grammar taught in grammar school, where words and groups of words are classified in terms of nouns, verbs, subjects, objects, and so on, and simple sentences are parsed in order to show the interrelation of their parts.

It is rather illuminating to consider some of the quantitative aspects of sentence structure. Of the 10^{100} arbitrary sequences of 20 words, perhaps only 10^{25} to 10^{30}, are actually English sentences. Practically all of the remainder are mere incoherent jumbles of words. Sentence structure thus places very strong constraints on the sequences of words. Another way of appreciating the degree of constraint imposed by sentence structure is to take a 20-word sentence from a newspaper and rearrange the words. Of the 20! different arrangements, only a few are English sentences. That there must be some structure or system underlying these constraints is apparent. A man in his lifetime would not be physically able to hear or speak more than 10^9 sentences, yet he can instantly recognize whether any given sequence of 20 words is included among the 10^{30} to 10^{50} English sentences or is left in the remaining 10^{100} ungrammatical jumbles of words. He can do this by recognizing whether or not the sequence conforms to one of the allowable sentence patterns. Recognition of sentence pattern is based primarily on formal features of the sequence and not on the meaning; for the meaningless lines by Lewis Carroll:

> 'Twas brillig, and the slithy toves
> Did gyre and gimble in the wabe:
> All mimsy were the borogoves,
> And the mome raths outgrabe.

are instantly recognized as conforming to English sentence patterns.

Constraints powerful enough to restrict the sequences of words to only those that conform to the sentence structures of a language can be represented by the following scheme. A set of structural choices is encoded into a sequence of words. The first step is to choose one of several possible sentence types. For English these might be:

sentence = 'I' + predicate a

or

sentence = 'you' + predicate b

or

sentence = subject c + predicate c

etc., or

sentence = 'it' + predicate p + 'that' clause

etc.

In this "sentence" stands for all sentences in English; "predicate a" stands for all predicates that can follow the first person, singular subject "I"; and so on. Take the example:

sentence = 'it' + predicate p + 'that' clause

This means that the sentence will start with the word 'it,' followed by a particular type of predicate, predicate p, and followed in turn by a clause introduced by the word 'that.' The particular predicate of type p and the particular 'that' clause will emerge as a result of further choices. For the predicate, the choices might be:

predicate p = verb 'to be' + adjective b

or

predicate p = verb 'to be' + prepositional phrase

or

predicate p = verb 'to be' + past participle c

etc.

The first of these might be chosen. Further choices would decide the tense of the verb, the present tense, for example. For the adjective, the choices might be:

adjective b = 'clear'

or

adjective b = 'true'

or

adjective b = 'likely'

etc.

If 'clear' is chosen, the sentence so far is: "It is clear + 'that' clause." Note that adjective b would not include adjectives like hot, red, small, and so on.

An encoding scheme of this sort can allow for certain types of recursiveness in sentence structure. For example:

It is clear that it was likely that it was true that...

This type of recursiveness is indicated by

'that' clause = 'that' + sentence

which leads back again to the beginning of the set of choices.

An encoding scheme of this sort, starting as it does with a set of choices or directions for producing a certain sentence and ending with the words of that sentence, can be thought of as a grammar of a language from the point of view of the speaker rather than of the listener. Schemes from the speaker's point of view have the advantage that each set of choices leads unambiguously to a unique sequence of words. On the other hand, a given sequence of words may be ambiguously represented by two or more different sets of choices. As an example of this, consider that

predicate a = 'am here now'

or

predicate a = 'see it now'

etc., and

predicate b = 'are here now'

or

predicate b = 'see it now'

etc.

Then 'see it now' can be produced ambiguously as a first-person singular or a second-person predicate. A grammar from the listener's point of view could resolve this ambiguity only by consideration of the context 'I' or 'you.' Similarly, words can have multiple meanings from a literal point of view, but be unambiguous if their role in the sentence structure is known. As an example, consider this English sentence:

The (Der) man showed the (dem) boy the (das) picture.

and this part of a German sentence:

Der (the) Mann, der (who) der (of the) Tat fähig ist,...

In this way, considerations of sentence structure can resolve many of the multiple-meaning problems.

Usually each possibility of choice of structure in a language has a meaning assigned to it. A distinction has been made between the "structural" meaning and the "lexical" meaning. The two sentences "The chair is on the rug." and "The rug is on the chair." have different meanings because the words appear at different positions in the structure. On the other hand, the difference in meaning between "The chair is on the rug." and "The chair is on the floor." is a lexical difference. Lexical meaning tells what sentences talk about; structural meaning tells what they say about it.

Just as different languages are different lexically, they can also be different structurally. Languages that are historically related are usually similar in structure. Even if two languages have certain structures in common, it may be that they assign different meanings to these structures. Languages may also differ in what aspects of the meaning are carried structurally and what aspects are carried lexically. The distinction between subject and object in a sentence is indicated structurally by word order in English, but in German it may be indicated by the lexical difference between *der* and *den*. Similarly the meaning that is assigned lexically to the word *if* in English, is sometimes indicated structurally by word order in German.

TRANSLATION OF STRUCTURE

If translation by machine is to be done on a sentence-by-sentence basis, grammars are needed for each language. The use of sentence structure to resolve word order and multiple-meaning problems and to translate the structural meanings correctly must be based on adequate grammars. These grammars should consist of descriptions of each language which are complete enough to make the distinctions in meaning necessary for translation. A description of this sort for even one language has not yet been provided, because the concepts involved are just now beginning to be understood and because languages are extremely complex in structure. Once two of these descriptions are available, they can be set side by side, and the equivalences stated. It must be decided which sentences in language *A* and language *B* are equivalent. The underlying assumption is that it is possible to find such correspondences. Of course, this assumption is not strictly valid, for no two languages are completely translatable. It is probably very nearly valid for related languages such as German, English, French, and Russian, and for scientific discourse, or other types of careful exposition.

If a description of the structure of two languages and a statement of the equivalences in meaning between them are given, only one more thing is needed for a mechanized translation procedure: a mechanical method of recognizing the structure of a sentence from the sequence of words composing the sentence. The precise form of this recognition routine must await the description of the structures to be recognized. However, the process must operate from the point of view of the person who reads or hears a sentence. It must tentatively recognize small groups of words, place them in a tentative structure, and so proceed, each time eliminating certain possibilities. Once the structure of the sentence to be translated has been recognized, it can be translated into an equivalent structure in the other language, and the correct meanings can be chosen from the multiple meanings of the words.

RESULTS EXPECTED

The translations produced by a routine that translates on a sentence-for-sentence basis will be vastly better than the output of a word-for-word translating machine. Most output sentences will be grammatically correct. There will be very few word-order problems remaining. Many of the multiple-meaning difficulties will be solved, particularly those involving the most frequent words of the language and the very frequent inflectional endings. There will be a partial solution to multiple-meaning problems such as the different meanings of *can* which are distinguished on the basis that one meaning is connected with a verb, one with an auxiliary verb, and one with a noun. Some multiple-meaning problems will remain. Of these, some can be resolved by judicious use of a field glossary or by related techniques. The rest must be resolved by the good sense and intelligence of the reader of the translation.

Conclusions

The state of the art of mechanical translation may be summed up in the following manner:

1. Word-for-word translations can be made now on high-speed, general-purpose, digital computers.

2. Word-for-word translations could be made more economically by means of special-purpose machines built with existing technology.

3. Word-for-word translations promise to be considerably cheaper than man-made translations.

4. Word-for-word translations are very crude, but may be useful when more accurate translations are not worth the additional cost.

5. If something better than a word-for-word translation is desired, the best procedure would be to take into consideration the sentence structure in designing a translation routine.

6. Providing translation routines on a sentence-for-sentence or structural basis requires a considerable amount of detailed linguistic work.

Integrated s-Plane Synthesis Using 2-Way Root Locus

JOHN ZABORSZKY
MEMBER AIEE

IN GENERAL, the design of automatic feedback control devices starts with two sets of data: 1. The specifications of the closed-loop performance such as the steady-state errors or error constants, minimum speed and maximum overshoot of the transient, bandwidth, etc., and 2. The known characteristics of physically existing components, combined into a plant which must become a part of the open loop of the control system.

It should be noted that group 1 defines certain characteristics of the closed loop, and group 2 certain characteristics of the open loop. This is unfortunate, mainly since the correlation between closed- and open-loop characteristics is shrouded in the difficulties of factoring polynomials and computing transients, and in the labor involved. The result is a certain amount of indirectness and lack of symmetry in the techniques which have been developed for the synthesis of automatic control systems.

Nomenclature

$c(t)$ or $C(s)$ = controlled output, Fig. 1
$r(t)$ or $R(s)$ = controlling input
$e(t)$ or $E(s)$ = error
$G(s) = G_1(s)G_2(s)$ = open-loop transfer function
$G_1(s)$ = transfer function of existing plant
$G_2(s)$ = transfer function of series compensating networks
$K(s)$ = closed loop transfer function
q_i $(i=1,2\ldots n)$ = poles of closed-loop transfer function, $K(s)$
w_i $(i=1,2\ldots m)$ = zeros of closed-loop transfer function, $K(s)$
z_i $(i=1,2\ldots \mu)$ = zeros of plant transfer function, $G_1(s)$
z_i $(i=\mu+1,\mu+2,\ldots m)$ = zeros of compensator transfer function, $G_2(s)$
p_i $(i=1,2\ldots r)$ = poles of the plant transfer function, $G_1(s)$
p_i $(i=r+1,r+2,\ldots n)$ = poles of the compensator transfer function, $G_2(s)$
K_e = closed-loop gain constant
K_0 = open-loop gain constant

Paper 56-981, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 1–5, 1956. Manuscript submitted March 26, 1956; made available for printing August 31, 1956.

JOHN ZABORSZKY is with Washington University, and consultant to the McDonnell Aircraft Corporation, St. Louis, Mo.

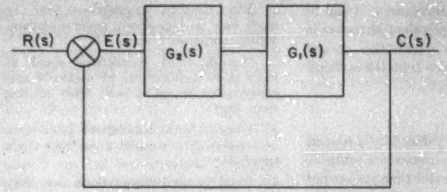

Fig. 1. Basic block diagram of a closed loop automatic control system with unit feedback

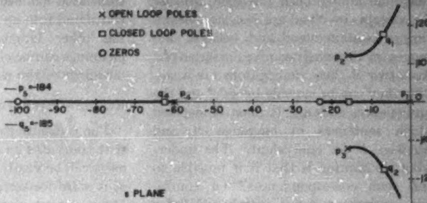

Fig. 2. Second root locus for illustrative example

K_d = displacement error constant
K_v = velocity error constant
K_a = acceleration error constant
T_p = time to reach first transient peak with step displacement input, Fig. 2
M = maximum transient overshoot with step displacement input
T_s = settling time of transient, to reach 2 per cent of initial displacement error
N = number of predominant oscillations in T_s
t = time
$s=\sigma+j\omega$ = complex frequency

$$\zeta=\frac{\sigma}{\sqrt{\sigma^2+\omega^2}},\quad \rho^2=\sigma^2+\omega^2$$

Discussion of Synthesis Techniques

Present synthesis techniques take one of two approaches: The historically older approach, as represented by the frequency response methods[1,2] of Nyquist, Bode, and Nichols, and by the root locus solution of Evans,[3] commences with the transfer function of the plant, and proceeds to estimate the corresponding closed-loop characteristics, the two being linked, (Fig. 1), by the relation

$$K(s)=\frac{G(s)}{1+G(s)} \tag{1}$$

If the closed loop characteristics fall short of the specifications, the open loop is supplemented by cascaded lead and lag compensating networks until satisfactory closed-loop performance is reached. However, the compensating networks must be preselected (for instance, lead or lag networks), rather than synthesized for the best achievement of the set goal in the closed loop. The objectives of the design are improvements in the closed-loop performance, yet the changes are made in the open-loop transfer function with no direct means, in most cases, to calculate what change to make to attain the goal.

The other approach[4] is the one proposed by Guillemin. This commences with the selection of poles and zeros of the closed-loop transfer function to conform to the specifications of steady, and transient, performance; bandwidth; etc. Once the closed-loop transfer function is chosen through its poles and zeros, the open-loop transfer function is determined by the inversion of equation 1 as

$$G(s)=\frac{K(s)}{1-K(s)} \tag{2}$$

This transfer function, then, is synthesized for the open loop with conventional network synthesis techniques.

This method in its original form can be used to determine open-loop transfer functions with real roots only, except through factoring equations of higher order. A more serious consideration is that it takes no advance cognizance of the plant and so yields and open-loop transfer function, the poles and zeros of which usually do not coincide with poles and zeros of the plant transfer function. The latter either must be cancelled by the compensating network of the open loop, or else the closed loop must be modified by shifting poles and zeros in it to cause poles and zeros of $H(s)$ in the open loop to coincide with those of the plant. The fact that the poles and zeros of the closed loop are less rigidly fixed than those of the plant probably accounts for the wider use of the methods in the first group.

General Synthesis Considerations

As may be observed, both of these approaches are somewhat one-sided; one is from the point of view of the open loop and the other from that of the closed loop. Yet the problem in its original form is highly symmetrical:

1. A set of specifications for the closed loop resulting in a desired transfer function $K(s)$ is given.
2. A set of components in the open loop combined into a plant with transfer function $G_1(s)$ is given.
3. A control network, or its transfer function $G_2(s)$, to match the foregoing two, is sought.
4. Open and closed loops are linked by the equation

$$K(s)+K(s)G_1(s)G_2(s)-G_1(s)G_2(s)=0 \tag{3}$$

Indeed, one of the most striking aspects of this statement of the problem is its symmetry, and it appears that the synthesis should not only take cognizance of this symmetry but should actually utilize it. A process to accomplish this will be discussed later in the paper.

Formalized Synthesis

It should be mentioned first that once the transfer functions $K(s)$ and $G_1(s)$ are fixed, the problem has only one solution for control network and it appears in a closed mathematical form as the solution of equation 3

$$G_2(s)=\frac{1}{G_1(s)}\,\frac{K(s)}{1-K(s)} \tag{4}$$

A corresponding network could be synthesized by conventional synthesis techniques.

A system so designed and, in general, only a system so designed would have exactly the closed-loop transfer function which was selected on the basis of the specifications and would at the same time incorporate the existing plant in the open loop. However, a closer study of equation 4 reveals that this is accomplished in an undesirable fashion. The term $1/G_1(s)$ in equation 4 means that in general the compensating network cancels every pole and zero of the plant by superimposing poles of $G_2(s)$ on the zeros of $G_1(s)$ and zeros of $G_2(s)$ on the poles of $G_1(s)$. Then, according to the second term on the right of equation 4, $G_2(s)$ introduces those poles and zeros into the open loop which are needed to produce $K(s)$. In other words, the existing open loop is cancelled and replaced by one to produce the selected closed loop. This could hardly be called an ideal method of synthesis.

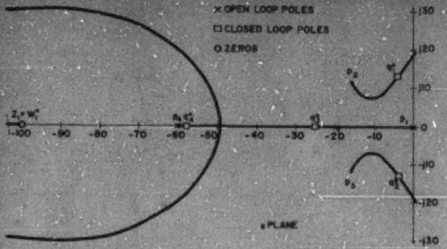

Fig. 3 (left). First root locus for illustrative example

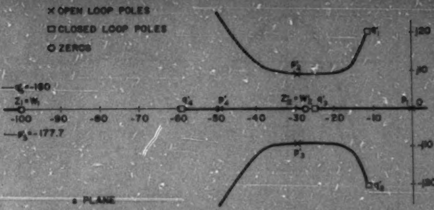

Fig. 4 (above). Reversed root locus for illustrative example

Integrated Synthesis

The breakdown of the formalized solution as a practical answer demands a more flexible interpretation of transfer functions $G_1(s)$ and $K(s)$. Actually, there may be some flexibility in the plant $G_1(s)$, and there certainly is substantial flexibility in the closed loop $K(s)$, since equally satisfactory closed-loop performance can be usually obtained by a number of various pole and zero configurations.

In this interpretation the closed loop and open loop are designed simultaneously to meet the specifications for both. The necessary flexibility is contributed by $K(s)$ in the closed loop and principally by $G_2(s)$ in the open loop, which still preserves the symmetry of the situation.

The solution itself can probably be best effected by an iteration process which fits the symmetry of the problem. The iteration can start either in the open or the closed loop. Suppose that the starting point is a $K(s)$ closed-loop transfer function which has been selected on the basis of the specifications.

1. The first step would be to prepare a reversed root locus according to Appendix II for the open-loop poles. If, now, the system is to be zero displacement error, a first-order pole in the open loop must be located at the origin. This pole fixes the closed-loop gain K_c and the latter locates all the other open-loop poles; see equation 26. Open-loop zeros coincide with closed-loop zeros, for unity feedback. See Fig. 1.

2. The open-loop poles and zeros thus obtained, of course, will not in general coincide with any of the poles and zeros of the plant, so the open-loop transfer function obtained must be modified. This will be done by shifting open-loop poles or zeros which are fairly close to poles and zeros of the plant to coincide with the latter. Where no pole or zero is close to those of the plant, poles and zeros are simply added in the open loop.

3. A conventional root locus for the closed-loop poles is now constructed on the basis of the revised open-loop poles and zeros, an open-loop gain is selected, and the poles of the closed loop are identified by conventional root locus techniques. Of course these poles will not now in general coincide with the starting set of step 1.

4. Consequently, modifications again must be made in the closed loop to meet specifications. First the specification values are evaluated from the results of step 3 and then poles and zeros are shifted according to need for meeting the specifications. The addition of further poles and zeros may be found necessary; this, of course, means a transition to a higher order $G_2(s)$ compensating network.

5. Open-loop poles and zeros are again obtained, as in step 1.

6. Poles and zeros of the plant are again moved back to where they belong, as in step 2.

7. Closed-loop poles and zeros again obtained, as in step 3.

8. Modifications in the closed loop made, as in step 4, etc.

Naturally the number of iterations actually required by a practiced designer will usually be small.

Clearly, the modifications in the closed loop must be selected and tailored to the individual case although there are some standard techniques[4,5,6] based on the equations of Appendix I.

As mentioned, the method is quite flexible as regards the starting point of the iteration. It can be started in the open loop rather than the closed with, for instance, the plant alone as the open-loop transfer function in the first step. Or it can be used to sharpen up a design obtained by some frequency response technique such as the Nyquist diagrams.

It should be noted that this proposed process still depends to a large extent on the experience and judgment of the designer. However, this is no deficiency, since it seems doubtful that a closed solution leading from the specifications of the two loops directly to the transfer function of a compensating network will ever be devised.

On the other hand, the proposed process does introduce symmetry and a higher degree of organization into the design, by substituting iteration for cut-and-try method. Looking at the problem from either the open or the closed loop the designer is forced to estimate what change to make in the loop selected for base in order to achieve a desired change in the other loop. But the 2-way use of root locus can answer the question as to what specific change should be made in either loop to effect a desired improvement in the other. Of course, there remains the compromise customary in engineering design as to how much of this change is permissible.

This presentation is on the basis of a unity feedback system; however, the extension to systems with networks in the feedback loop is obvious. Equally obvious is the adaptation of the use of other types of diagrams designed to locate roots.[7]

Illustrative Example

The advantages of the proposed method are apparent mainly in complex problems where the designer is likely to lose insight for the change required, for instance, in the open loop, in order to produce a desired improvement in the closed loop, or vice versa. In such cases the 2-way use of the root locus can supply the needed information. However, since complex problems would be unreasonably long and unwieldy for publication, only a simple illustrative example is presented here which could be solved with about equal ease by conventional techniques. Consequently, this example should be considered illustrative only in the sense of showing the steps in the process and not in the sense of demonstrating its usefulness.

Following are the specifications for the performance of a closed-loop automatic control system:

$K_a = \infty$
$K_v \geq 10$
$M \leq 25$ per cent
$T_p \leq 0.2$ second
$T_s \leq 1$ second
$\omega_{bw} \leq 30$ radians per second

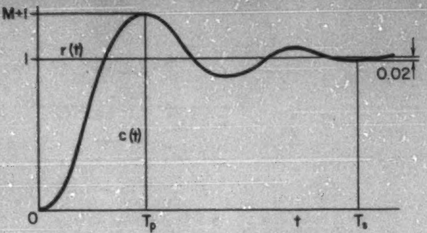

Fig. 5. General sketch of a transient response

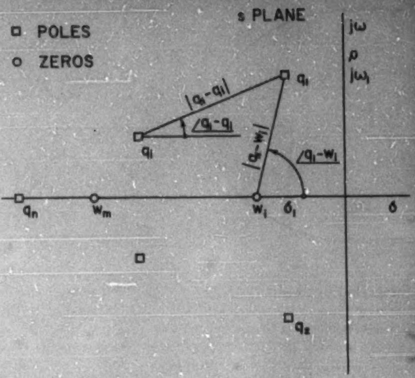

Fig. 6 (right). Closed-loop poles and zeros

The system must incorporate in its open loop a plant with the transfer function of

$$G_1(s)=\frac{s-z_1}{s(s-p_2)(s-p_3)(s-p_4)}$$

$$=\frac{s+100}{s(s+16-j12)(s+16+j12)(s+60)}$$

In this example the design is started by ascertaining the optimum performance possible without any compensating network. For this purpose a root locus based on poles p_1, p_2, p_3, and p_4, and zero z_1 of the plant itself, is constructed in Fig. 3. Now, an open loop gain of $K_0''=2{,}750$ is selected, which locates the closed loop poles at $q_1''=-4+j13$, $q_2=-4-j13$, $q_3''=-25$ and $q_4''=-57.7$. A closed-loop zero is present at $w_1''=z_1=-100$. The values involved in the specifications can now be evaluated by the equations of Appendix I; yielding

$K_d=\infty$
$K_v=6.25$
$M=31$
$T_p=29$
$T_s=1$ second
$\omega_{bw}=17$ radians per second

While these represent the optimum compromise which can be obtained from the plant alone simply by adjusting the gain, they do not satisfy the specifications. Consequently, the system will have to be modified by shifting the predominant pair of poles away from the origins and to the left into the position of $q_1'=-12.5+j20$ and $q_2'=-12.5-j20$. An additional zero will be required to make such shift possible; this will be placed to $w_2'=-27.5$. Finally, an additional pole is introduced at $q_5''=-180$ to maintain the excess of three in the number if poles over the number of zeros or, in other words, to avoid a compensating network with a pole at infinity. The other poles and zeros are left unchanged at $q_3'=q_3''=-25$, $q_4'=q_4''=-57.7$ and $w_1'=w_1''=z_1=-100$. The specification values for this set of closed-loop poles and zeros, as shown in Fig. 4, are

$K_d=\infty$
$K_v=16.8$ per second
$M=12$ per cent
$T_p=0.176$ second
$T_s=0.87$ second
$\omega_{bw}=26.5$ radians per second

These satisfy the specifications with some margin. Now, a revised root locus is constructed in Fig. 4, and the open-loop poles are established after the closed loop gain of $K_e=52{,}000$ is found from the condition of $p_1=0$, which is required by $K_d=\infty$. The resulting open-loop poles $p_2'=-29.9+j8$, $p_3'=-29.9-j8$, $p_4=-49$, and $p_5'=-177.7$, fail to coincide with the poles of the plant.

The next step is to move poles p_2', p_3', p_4' to coincide respectively with poles p_2, p_3, and p_4 of the plant, as shown in Fig. 2. To compensate for this move, zero w_2' is also moved to $w_2=z_2=-23$. The root locus constructed in Fig. 2 then yields with a gain of $K_0=2{,}700$, a new set of closed-loop poles at $q_1=-7+j17.5$, $q_2=-7-j17.5$, $q_3=-15.5$, $q_4=-62.5$, $q_5=-185$. These give

$K_d=\infty$
$K_v=13.1$ per second
$M=24.5$ per cent
$T_p=0.20$ second
$T_s=0.6$ second
$\omega_{bw}=23$ radians per second

These are within the specifications; consequently the iteration can now be discontinued. The compensating network is then represented by gain $K_0=2{,}700$, the pole $p_5=-184$, and the zero $z_2=w_2=-23$. Therefore

$$G_2(s)=2{,}700\,\frac{s+23}{s+184} \tag{5}$$

a simple lead network for this simple problem.

Conclusions

A viewpoint is presented, which gives more consideration than does the conventional viewpoint, to the double nature and the symmetry of closed-loop control system synthesis, with the controller as an element to match a set of specified components in the open loop to a set of performance specifications in the closed loop.

Also presented is a method of synthesis which assigns symmetrical roles to the specifications for open and closed loop in the design of a controller whether the method is used for design directly from the specifications or for refining a design for a controller which was obtained by conventional methods.

Appendix I. Selection of Closed-Loop Poles and Zeros

The basis of any selection of closed-loop poles and zeros must clearly be the relationships which exist between the pole and zero locations of the closed loop and such items of the performance specifications as bandwidth, steady-state errors or error constants, transient overshoot, and the speed and attenuation of the transient response. Such relationships have been developed and are summarized here. If the closed-loop transfer function is denoted, Fig. 1

$$K(s)=\frac{C(s)}{R(s)}=\frac{G_1(s)G_2(s)}{1+G_1(s)G_2(s)}$$

Vol. 7
Pt. 1
1956

$$= \frac{K_d}{1+K_d} - \frac{1}{K_v}s - \frac{1}{K_a}s^2 \ldots \quad (6)$$

or

$$K(s) = K_c \frac{(s-w_1)(s-w_2)\ldots(s-w_m)}{(s-q_1)(s-q_2)\ldots(s-q_n)} \quad (7)$$

Then, the steady-state errors, or rather the error constants, are determined as[4]

$$K_d = \frac{K_c \prod_{i=1}^{m} w_i}{(-1)^{n-m} \prod_{i=1}^{n} q_i - K_c \prod_{i=1}^{m} w_i} \quad (8)$$

$$\frac{1}{K_v} = \sum_{i=1}^{m} \frac{1}{w_i} - \sum_{i=1}^{n} \frac{1}{q_i}, \text{ if } K_d = \infty \quad (9)$$

$$\frac{1}{K_a} = \frac{1}{2}\left(-\frac{1}{K_v^2} \sum_{i=1}^{n} \frac{1}{q_i^2} + \sum_{i=1}^{m} \frac{1}{w_i^2} \right), \quad \text{if } K_d = \infty \quad (10)$$

The main characteristics of the transient response are determined,[5,8] Fig. 5

$$T_p = \frac{1}{\omega_0}\left(-\sum_{i=1}^{m} \underline{/q_1 - w_i} + \sum_{i=3}^{n} \underline{/q_1 - q_i} \right) \quad (11)$$

$$M = \prod_{i=1}^{m} \frac{|q_1 - w_i|}{|w_i|} \prod_{i=3}^{n} \frac{|q_i|}{|q_1 - q_i|} e^{-\sigma_1 T_p} \quad (12)$$

$$T_s = \frac{4}{\zeta \rho} \quad (13)$$

$$N = \frac{2}{\pi} \frac{\sqrt{1-\zeta^2}}{\zeta} \quad (14)$$

It is assumed for equations 11 through 14 that the closed-loop transfer function has a predominant pair of poles, i.e., two conjugate complex poles q_1 and q_2, Fig. 6, the real parts of which are much smaller (preferably at least one-third smaller) than the real part of the next pole; see Fig. 6. The assumption is justified because this type of arrangement is known to be the most desirable and also because it alone is amenable to reasonably simple evaluation on the basis of closed-loop poles and zeros. However, relations have been published for evaluating closed-loop response for systems without predominant poles.[8,9]

Bandwidth is defined as the frequency, ω_{bw}, where the closed-loop amplitude drops to $1/\sqrt{2}$ of its zero frequency value. It is the solution of the equation

$$1/\sqrt{2} = K_c \frac{\prod_{i=1}^{m} |j\omega_{bw} - w_i|}{\prod_{i=1}^{n} |j\omega_{bw} - q_i|} \quad (15)$$

or, approximately on the basis of the predominant roots only

$$\frac{\omega_{bw}^2}{\zeta^2} = (1-2\zeta^2) + \sqrt{2-4\zeta^2+4\zeta^4} \quad (16)$$

It must be remembered further that $G(s)$ must have an excess of poles over zeros, $(n-m)$, which is not smaller than the excess of poles over zeros in the given plant $G_1(s)$, unless the compensating network $G_2(s)$ is to have a pole at infinity.

The spirule[3] is a useful tool in evaluating equations 8 through 12 and solving equation 15. When the specifications for the closed-loop performance are given, closed-loop pole and zero locations can be selected by the aid of equations 8 through 15 to satisfy these specifications. This process has been discussed and illustrated[4,5,6] and will not be further discussed here.

Appendix II. Reversed Root Locus

According to equation 2, the only poles of the open-loop transfer function will be where

$$1 - K(s) = 0 \quad (17)$$

or

$$K(s) = 1 \quad (18)$$

This complex equation is equivalent to the following two real equations

$$\underline{/K(s)} = 0 \quad (19)$$

$$|K(s)| = 1 \quad (20)$$

or with equation 7

$$\sum_{i=1}^{m} \underline{/s - w_i} - \sum_{i=1}^{n} \underline{/s - q_i} = 0 \quad (21)$$

$$K_c \frac{\prod_{i=1}^{m} |s - w_1|}{\prod_{i=1}^{n} |s - q_1|} = 1 \quad (22)$$

Equation 19, or equation 21, of course, describes a root locus on which the sum of the angles is 0 degrees rather than 180 degrees. Like the conventional root locus, this too can be established by the spirule[3] or by phase-angle loci.[6]

Some helpful characteristics in establishing the reversed root locus are as follows:

1. The locus is symmetrical with respect to the real axis.

2. Branches of the locus terminate at closed-loop poles and zeros or at infinity.

3. The number of branches going to infinity equals $n-m$, the excess of closed-loop poles over closed-loop zeros if $m<n$. (23)

4. The branches going out to infinity will approach asymptotes which made the following angles with the real axis

$$k\frac{360}{n-m} \quad (24)$$

where $k = 0,1,2,\ldots(n-m-1)$ and $m<n$.

5. There is always at least one branch $(k=0)$ going to infinity. This branch is the section of the real axis lying to the right of the extreme right real pole or zero of $K(s)$.

6. All asymptotes meet at one point on the real axis, i.e., at the centroid

$$\frac{\sum_{1}^{n} Re|q_i| - \sum_{1}^{m} Re\,|w_i|}{n-m} \quad (25)$$

7. The initial angle of the locus at a complex pole is the sum of the angles of all vectors connecting all poles and zeros to the complex pole in question. Angles of vectors from zeros are taken positive and those from poles are taken negative.

8. The initial angle of the locus at a complex zero is equal to the sum of the angles of all vectors connecting all poles and zeros to the complex pole in question. Angles of vectors from zeros are taken negative and those from poles are taken positive.

9. At real single poles or zeros the locus starts along the real axis.

10. At real double poles or zeros the two branches of the locus start either along the real axis or perpendicular to it.

11. At very low closed-loop gain the open-loop poles almost coincide with the closed-loop poles, and with increasing gain they gradually shift to the closed-loop zeros or to infinity. The number of closed- and open-loop poles is the same, with unity feedback, Fig. 1, and $m<n$.

Since the preparation of this paper an extensive study[10] of the reversed root locus has been presented.

Design of Wide-Band R-F Transformers Utilizing a Synthesized Equivalent Network

HITOSHI H. KAJIHARA
NONMEMBER AIEE

Synopsis: Design considerations of wide-band r-f (radio-frequency) transformers operating over a frequency range of 10 to 100 mc (megacycles) are reviewed. The complete basic equivalent circuit representation of transformers must be used in the analysis of the input impedance characteristics. A synthesized equivalent network is used in determining the critical transformer parameters. Experimental data and characteristics of a 25-watt, 20- to 70-megacycle unit are presented.

THE FLEXIBILITY of impedance transformation ratio, ease of fabrication, and physical compactness are inherent advantages of transformers. These factors favor its use over other methods of coupling antennae to transmitters. The knowledge of these transformer attributes and the recent development of low-loss ferrite core materials led to the investigation and realization of the 20- to 70-mc wide-band r-f transformer described in this paper. In conjunction with the development of this unit, a method of determining the critical transformer design parameters and of predicting its VSWR (voltage standing wave ratio)-bandwidth performance was formulated. It is the purpose of the paper to introduce this method of wide-band r-f transformer design, to review the design considerations of a specific r-f transformer, and to present experimental information useful in designs of other r-f units.

Discussion

A 25-watt, 20- to 70-mc r-f transformer was required to match a 92-ohm coaxial cable to a 1,200-ohm whip antenna. A maximum VSWR of 2, and a minimum efficiency of 80 per cent were required of the transformer. A satisfactory unit meeting these specifications was fabricated and field tested. Among the items of prime importance in obtaining a satisfactory unit were: 1. the input impedance characteristics to meet the VSWR requirements, 2. low core loss material, 3. the best winding arrangement for optimum coupling, and 4. the selection of conductors.

VSWR and Input Impedance Characteristics

Since the VSWR becomes of prime concern for satisfactory transmission of signals at these frequencies, the input impedance characteristic of the r-f transformer assumes primary importance. A typical input impedance characteristic of a terminated r-f transformer is shown in Table I. These impedances are given in terms of parallel resistive R_p and reactive X_p components. Examination of Table I shows that at the lower frequencies, the R_p is larger than the reflected load resistance R_L calculated on a turns-ratio-squared basis. The X_p is inductive. With increasing frequency, R_p decreases in magnitude. A frequency is reached where the input impedance becomes purely resistive. Above this frequency, the reactive component becomes capacitive. A second frequency is obtained where the input impedance is again purely resistive. Above the second resonant frequency, the reactive impedance becomes inductive. This input impedance characteristic can be duplicated by an equivalent network consisting of seven elements.

The schematic diagram of these transformers is shown in Fig. 1. The input impedance in terms of parallel resistive and reactive components is given by equations 1 and 2

$$R_p=\frac{A^4+\left\{B\left[C^2+\left(\frac{C}{D}-1\right)^2\right]-A^2\left[C+\frac{1}{D}\left(\frac{C}{D}-1\right)\right]\right\}^2}{A^2\left\{C^2+\left(\frac{C}{D}-1\right)^2\right\}}R_L \qquad (1)$$

$$X_p=\frac{X_{c1}X_p'}{X_{c1}-X_p'} \qquad (2)$$

where

$$X_p'=\frac{A^4+\left\{B\left[C^2+\left(\frac{C}{D}-1\right)^2\right]-A^2\left[C+\frac{1}{D}\left(\frac{C}{D}-1\right)\right]\right\}^2}{B\left\{C^2+\left(\frac{C}{D}-1\right)^2\right\}\times\left\{B\left[C^2+\left(\frac{C}{D}-1\right)^2\right]-A^2\left[C+\frac{1}{D}\left(\frac{C}{D}-1\right)\right]\right\}}X_{L1}$$

and

$$A=\frac{X_M}{R_L}$$

$$B=\frac{X_{L_1}}{R_L}$$

$$C=\frac{X_{L_2}}{R_L}$$

$$D=\frac{X_{c_2}}{R_L}$$

Synthesis of Equivalent Network

The simplest network which can make the reflected load resistance appear larger than the value calculated on a turns-ratio-squared basis is a network shown in Fig. 2. The resistive component is given by equation 3

$$R_p=\left\{1+\left(\frac{X_s}{R_L}\right)^2\right\}R_L \qquad (3)$$

To make R_p even larger, a capacitance C_0 can be placed in parallel with X_s. In the transformer, C_0 represents the direct capacitance from secondary to primary. The network is shown in Fig. 3. The R_p is given by equation 4

$$R_p=\left\{1+\left(\frac{X_s'}{R_L}\right)^2\right\}R_L \qquad (4)$$

where

$$X_s'=\frac{X_{c_0}X_s}{X_{c_0}-X_s}$$

A network which exhibits a characteristic of reducing R_p with increasing frequency over a range of frequencies is shown in Fig. 4. Beyond some frequency R_p will again increase. The R_p is given by equation 5

$$R_p=\left\{\left(\frac{X_s'}{R_L}\right)^2+\left(\frac{X_s'}{X_{c_2}}-1\right)^2\right\}R_L \qquad (5)$$

Paper 56-970, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 1-5, 1956. Fig. 2. Network for $R_p/R_L > 1.0$

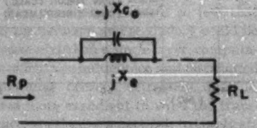

Fig. 3. Network for $R_p/R_L > 1.0$

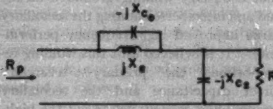

Fig. 4. Network for $R_p/R_L \leqslant 1.0$

To decrease R_p at the same rate as the actual r-f transformer, it was necessary to insert an equivalent core loss resistance in the network of Fig. 4.

The sign of the reactive component of the input impedance is determined by the primary self-inductance L_1, the primary distributed capacitance C_1, the leakage inductance and direct capacitance combination, and reflected secondary capacitance C_2. To duplicate the r-f transformer reactive impedance characteristics, an L_1 and C_1 is inserted in Fig. 4. Thus, the equivalent network which closely duplicates the r-f transformer impedance characteristics is shown in Fig. 5. It is recognized that this network is the complete basic equivalent network representation of transformers upon which simplifications are made for design of audio transformers. In r-f transformers whose coefficient of coupling is less than unity, similar simplifications cannot be made. Since the major portion of the elements in the equivalent network representation are parallel elements, it is convenient for computation purposes to convert the series leakage inductance and direct capacitance to equivalent parallel elements. If this conversion is performed, the circuit of Fig. 6 is obtained.

The leakage inductive impedance, reflected secondary capacitive impedance, and reflected load resistance are modified by K_0, K_1, and K_2, respectively.

$$K_0=\frac{\left(\frac{X_e'}{R_L}\right)^2+\left(\frac{X_e'}{X_{c_2}}-1\right)^2}{\left(\frac{X_e'}{R_L}\right)^2\left\{1+\left(\frac{R_L}{X_{c_2}}\right)^2\right\}} \tag{6}$$

$$K_1=\left(\frac{X_e'}{R_L}\right)^2+\left(\frac{X_e'}{X_{c_2}}-1\right)^2 \tag{7}$$

$$K_2=K_1 \tag{8}$$

To calculate the numerical values of R_p and X_p of Fig. 6, it is simplest to use the input admittance equation. This is given by equation 9

$$Y_p=\frac{1}{R_p}-j\frac{1}{X_p}=\left(\frac{1}{K_2R_L}+\frac{1}{R_{c_1}}\right)-j\left(\frac{1}{X_{L_1}}-\frac{1}{X_{c_1}}+\frac{1}{K_0X_e'}-\frac{1}{K_1X_{c_2}}\right) \tag{9}$$

The substitution of typical r-f transformer parameter values in equation 9 shows that the first resonant frequency is determined primarily by the primary self-inductance and the distributed capacitances. This is a parallel resonance in Fig. 5, and the transformer performance is not affected. The second resonant frequency is determined primarily by the leakage inductance and direct capacitance. This is a series resonance in Fig. 5. It is detrimental to transformer performance from the power transfer consideration. Consequently, for wide-band operation of transformers it is very important to minimize these two parameters.

CONSTRUCTION OF EQUIVALENT NETWORK

The R_p and X_p measurements of a terminated r-f transformer are made over the appropriate frequency range. If at the lower frequencies the R_p is larger than R_L, leakage inductance is present. The leakage inductance may be measured by one of two methods. The first method is the conventional bridge measurement technique with the secondary winding short-circuited. A Q meter may also be used for the measuring instrument. A second method is to measure the self-inductances of the windings, and the series-aiding and series-opposing inductances of the two windings on an RX (resistance-reactance) meter or a Q meter. From these measurements, the mutual inductance is calculated and the leakage inductance determined.

In all the inductance measurements at high frequencies, corrections may be neces-

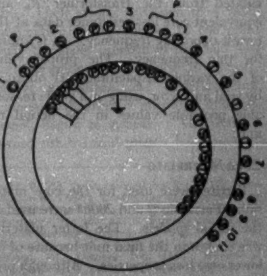

Fig. 7. Winding arrangement of final r-f transformer

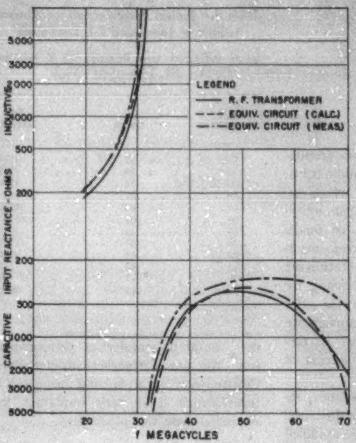

Fig. 8 (left). Input reactive impedance characteristics of r-f transformer and synthesized network

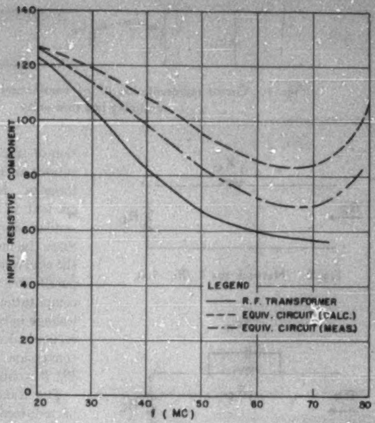
Fig. 9 (right). Input resistive characteristics of r-f transformer and synthesized network



sary because of distributed capacitance effects. The measurements should be made at several frequencies, a minimum of two. The true inductances and distributed capacitances can be calculated with equations 10 and 11. The subscripts 1 and 2 refer to two frequencies f, where f_2 is greater than f_1.

$$L_{\text{act}} = L_{\text{meas2}} \frac{1-\left(\frac{f_2}{f_1}\right)^2}{1-\frac{L_{\text{meas2}}}{L_{\text{meas1}}}\left(\frac{f_2}{f_1}\right)^2} \tag{10}$$

$$C_d = \frac{L_{\text{meas1}} - L_{\text{act}}}{L_{\text{meas1}} \times L_{\text{act}}(2\pi f_1)^2} \tag{11}$$

For the purpose of obtaining an approximate leakage inductance for the equivalent network, it is simpler and quicker to use equation 3, and a value of R_L calculated on a turns-ratio-squared basis. The value of the reflected load resistance for use in the equivalent network is calculated from the transformer R_p and equivalent core loss resistance data at the lowest operating frequency. L_1 is known for this frequency. The proper value of the various capacitances is obtained by trial and error, using as a guide reasonable probable values in the actual r-f unit.

Core Materials

Ferrites were used for the core material. Ferramic *Q* and *2006** were used in the initial models. The latter material was chosen in the final unit because of its lower core loss properties. Although precise core loss measurement was not attempted at actual operating flux condition, the core temperature rise above ambient was noted. The relative temperature rise of *2006* to Ferramic *Q* at 70 megacycles and 10 gausses was about one to five. The core temperature rise of *2006* was 15 degrees centigrade.

Winding Arrangement

Various winding arrangements were investigated to obtain maximum coupling. A schematic diagram of the winding arrangement used in the final model is shown in Fig. 7. This arrangement yielded best performance. It was found that a tertiary winding grounded at one end and interspersed among the secondary turns improved high-frequency performance. It is believed that this winding reproportions the primary-to-secondary direct capacitance and the secondary interwinding capacitance to aid the high-frequency operation.

Selection of Conductors

The basic equation for the depth of penetration of current d_p into conductors was used as a guide in the selection of conductors. This equation neglects prox-

imity effects but extreme exactness is perhaps unwarranted here. The relationship is given by equation 12.

$$d_p = \frac{2.61}{\sqrt{f\text{mc}}} \text{ mils} \tag{12}$$

With the use of equation 12, a wire diameter is calculated so that the current density in the peripheral area is 200 circular mils per ampere.

DESIGN OF 25-WATT UNIT

The primary concern was to maintain low leakage inductance. This suggests keeping the turns to a minimum and investigating the optimum winding arrangement. Since the total turns required from the flux consideration were so few that both the primary and secondary could be accommodated on a single layer, computation of leakage inductance and distributed capacitance became extremely difficult. It was more expedient to wind the transformer, synthesize a network to duplicate its impedance characteristics, and then study the latter to determine, and make readjustment of, the critical transformer parameters. The network which was finally obtained to duplicate the transformer is shown in Fig. 5. The winding and core data of the final model are summarized as follows.

Core material: *2006*.
Core size: $1^{15}/_{16}$-inch outside diameter, $1^{7}/_{16}$-inch inside diameter, 3/8-inch height.
Number of cores: 2 per unit.
Primary turns and wire size: 3 turns of No. 14, 3 in parallel.
Secondary turns and wire size: 11 turns of No. 14, single.

EXPERIMENTAL DATA

The values of the components used to simulate the actual transformer are as follows, in μh (microhenrys) and $\mu\mu f$ (micromicrofarads):

$L_1 = 1.0\ \mu h$
$L_e = 0.15\ \mu h$
$C_0 = 10.0\ \mu\mu f$
$C_1 = 20.0\ \mu\mu f$
$C_2 = 15.0\ \mu\mu f$
$R_L = 134.0$ ohms

The input impedance characteristics of the actual unit and the measured and calculated impedance characteristics of the equivalent network are shown in Figs. 8 and 9. The R_p measurements on the equivalent network were taken without incorporating an equivalent core-loss resistive component since a different value is required at each frequency. This accounts for the discrepancy between the R_p of the equivalent network and the r-f unit. The VSWR-versus-frequency characteristic of the r-f transformer is shown in Fig. 10.

MEASUREMENT TECHNIQUES

An *RX* meter was used to measure the R_p and X_p. The VSWR was calculated from the Smith chart and also measured under actual operating conditions. Measurements at rated power were obtained by using Signal Corps *AN/TRC* transmitters. A specially constructed copper tubing with a center conductor was used to simulate a 92-ohm coaxial cable. The length was over a quarter wave length at the lowest frequency. Holes were perforated every 6 inches along the tube to permit entrance of a voltmeter probe for VSWR measurements.

Conclusions

The complete basic equivalent circuit representation of transformers must be used in the design and analysis of r-f transformers whose coefficient of coupling is less than unity. The critical design parameters may be established either by calculations or measurement on this network.

To obtain wide-band operation of r-f transformers in the 10- to 100-mc region the primary consideration is to minimize the leakage inductance and the primary-to-secondary direct capacitance.

The Communication Engineer's Needs in Information Theory

W. T. REA
MEMBER AIEE

Synopsis: Closer rapport between the mathematician and the communications engineer would permit information theory to be exploited more effectively. Improvement in the number and type of educational courses, symposia, and publications is recommended. Some examples are discussed of gaps in the theory which now handicap its application.

THE COMMUNICATION engineer should rely heavily upon information theory in planning new communication systems. Before its advent, much of what he did was likely to be intuitive. He knew, or sometimes "sensed," that certain choices led to superior results, but he had no satisfactory standard against which to measure the performance of the systems he designed nor an adequate method of comparing them, with any degree of rigor, against other possible systems.

Although Nyquist[1,2] and Hartley[3] laid the foundations of information theory during the mid-1920's, too few communications engineers became familiar with their work and its implications to exert a profound impact upon communications technology. But the comprehensive formulation which this theory received in the work of Shannon[4] and Wiener[5] in 1948 moved the art of communications a long step toward the status of a science. Since that time, a considerable number of mathematicians possessing great power and insight have been operating in this field. Their efforts have led to a rapid ramification of the subject to the point where the sheer breadth of the field now tends to present an obstacle to comprehensive exposition and understanding. Some specialization is indicated and has, indeed, begun to appear. The trend is toward subdivision[6] into:

Fig. 2. Two-way communication

1. Basic theory, for the mathematician interested primarily in the further development and extension of the subject.

2. Coding theory, of chief interest to the coding expert and the cryptographer.

3. Communication (modulation) theory, for those engaged in the synthesis and analysis of communication systems.

4. Biophysical theory, for the biophysicist, the experimental psychologist, the neurophysiologist, and the specialist in human engineering.

5. Linguistic theory, which appeals to the semanticist, the comparative philologist, and the researcher into the origins of language.

Indeed, the proceedings of some information theory symposia seem to encompass the areas of feedback and computers.

The second and third areas just listed are of principal interest to the communications engineer, and he has benefited greatly from the principles established. However, when he tries to use the mathematician's work as a guide in synthesizing, developing, and designing new systems, he is likely to find it incompletely applicable to his problems, and to wish that he either knew more or had access to an expert consultant.

With so many aspects of modern life dependent upon efficient communication, it seems important to do whatever may be necessary to improve the applicability and increase the utilization of information theory in the communications art. One need that has become evident is for more and better courses in Information Theory. Although a scattering of courses in the subject has been instituted at the graduate level, many more are needed here, as well as some at the undergraduate level if engineering graduates in the communications option are to be equipped with the basic techniques they so vitally need.

More ready access to new results in information theory would be helpful. Much has already been accomplished in this direction by annual symposia, the proceedings of which have been published and, in some cases, distributed to members of technical groups. However, more and better papers are needed for delivery at technical meetings and publication in technical magazines. A particularly evident gap exists in the literature; only one or two comprehensive books on the subject have been published.

A related need is for more thorough exposition. The new results attained by the mathematician's work in the field must be developed and processed to elucidate their application to specific situations. Interpreters of the experts must bring the important principles of information theory within the engineer's frame of reference by expressing them in terminology meaningful to him. The more specialized and abstruse the new work becomes, the more such exposition is needed. It is important that publication of tutorial papers should follow, without too great a lag, the appearance of significant original results.

For maximum benefit to the user, and through him to the world at large, the subject must be developed in directions useful in the communications art. Light must be thrown into the theory's dusty corners. Gaps must be filled that now stand as obstacles in the way of the user.

Some examples are discussed in the remainder of this paper.

Two-Way Communication

In dealing with practical communication situations, it is often difficult to relate their mode of action with that of the mathematical models upon which information theory is based.

One of these models is depicted in Fig. 1. It postulates an information source that emits, presumably in response to some series of stimuli, a flow of messages. At some destination the messages are interpreted in accordance with a set of conventions upon which the source and the destination have previously agreed. The quantity of information each message contains is defined as the negative of the logarithm of the probability of the particular message being emitted. Presumably the less probable messages will be more unexpected to the destination, and will thus impart more information. But it is worth noting that the unexpectedness of any message will, in some sense, depend upon the comprehensiveness of the conventions agreed upon.

The channel that transfers the messages from source to destination comprises an encoder which translates messages into signals, a noise source interfering with the signals, and a decoder translating the sum of signal and noise into messages. The capacity of the channel is affected by the conditional probability of the same message being received as that which was sent.

In actuality, the most common communication process functions in the manner illustrated by Fig. 2. This involves an interchange of messages between two individuals, each of whom includes an information destination coupled with an information source. During the 2-way communication process, which has strong feedback coupling, the "conventions" are continually changing, and the messages emitted are strongly influenced by the information content of previously received messages. This 2-way flow acts both to correct transmission errors and to remove imperfections from the structure of conventions.

If it is assumed that such a process has the purpose of maximizing some benefit, such as the knowledge of one or both of the participants, or enlarging their area of agreement, its theoretical treatment might involve a number of disciplines, such as:

1. Decision theory, in the coupling from destination to source.
2. Game theory, for, conceivably, the joint action to maximize mutual gain might be treated as a non-zero-sum game.
3. Feedback theory, which would be involved by the dynamics of the process.
4. Communication theory, needed for the efficient employment of the communication channel.

The step from the unidirectional to the bidirectional model is a large one and it may prove difficult. However, it is much needed and it offers a challenging opportunity for mathematical research. It is not impossible that the regrettable trend toward 1-way communication systems in the military, commercial, and administrative fields may be influenced by the concentration of theory on unidirectional principles and the lack of a bidirectional theory. Certainly this trend evidences insufficient appreciation of the importance of 2-way communication in reducing error and promoting understanding.

Once success has been attained in working out a comprehensive theory applicable to bidirectional systems, extension to multiway systems (which have interesting properties of their own) will very likely be found relatively easy.

Role of Delay

One of the facets of information theory most meriting investigation bears on the role of delay. A principle laid down by Shannon states that as the efficiency of communication is increased by removing redundancy, more delay is incurred in the encoding and decoding processes. This is somewhat analogous to the delay that accumulates as the transmission band of a wave filter is narrowed.

In actual practice, the usefulness of information often depends upon its freshness. Because delay handicaps 2-way communication, it would be helpful to the communications engineer if the theory provided a quantitative measure of the amount of delay that must be incurred in order to obtain a given improvement in the efficiency of communication. A promising start in this direction has recently been made by Shannon.[7,8]

Meaning and Utility of Information

The concept of quantity of information, as based on statistical or probabilistic grounds, is usually adequate in dealing with transmission systems. However, when the communications engineer becomes concerned with the larger systems that gather, transmit, process, and display information, he may find himself faced with problems that involve the meaning or the value of information. For example, he must avoid choices that deteriorate meaning or value. Delay, as mentioned, may be an important parameter affecting the value of information.

Until comparatively recently, the theory has tended to ignore such matters. Possibly some principles useful in dealing with the meaning or utility of information might be uncovered in an attack on the problem of 2-way communication. For example, since the utility of information depends upon its relevance, high value may require an optimum degree of cross-correlation with information previously received or stored. Too low a degree would intimate irrelevance, whereas too high a degree would indicate excessive redundancy. Recent work[9] by MacKay relates "meaning" to the change in the recipient's "conditional probability matrix."

Digital Codes for Reducing Magnitude of Error

In sending quantitative information by pulse code modulation, the instantaneous magnitude of a parameter is usually encoded as an n-digit binary number. A binary signal representing this number is then modulated onto some carrier wave for transmission.

A transmission error in the signal element associated with the most significant digit of the binary number will cause an error of half the maximum magnitude, whereas an error affecting the least significant digit will produce an error of only $1/2^n$ the maximum. Thus the signal element representing the most significant digit bears 2^{n-1} as much burden as that representing the least significant digit.

It does not seem proper that elements bearing different burdens should be equally susceptible to error. In a well-designed transmission system, it might be preferable to have each portion of the signal protected against error to an extent roughly proportional to the burden it bears, so that failure would be more likely to occur simultaneously over the whole transmission system. The discrepancy between burden and protection might be alleviated by distributing the burden more equitably or by strengthening the portions carrying heavier burdens.

For example, to distribute the burden more equitably, the permutations available in the code might be associated with the various possible magnitudes of the parameter in such a way as to reduce the consequences of the more probable sorts of error. Some examples of codes of this sort have been worked out by Kautz,[10] who cites them as having a low "confusion rating" because the more probable sorts of error will do comparatively little damage to the message. A set of general rules is needed for deriving codes of this sort, applicable to linear and circular scales of various degrees of precision. Also, much theoretical work is needed in evaluating the transmission improvement attainable by exploiting the principle of proportionality between protection and burden.

Abnormally Distributed Noise

Communications engineers often feel the need for methods of dealing with the effects of noise having a statistical distribution of amplitudes that is neither Gaussian nor Rayleigh. Many actual communication media are subject to "spiky" or "impulse" noise. Theoretical study of such cases would be greatly facilitated by the development of a readily manipulable analytic function to represent an amplitude distribution characteristic of this sort of noise.

Conclusions

To bridge the gap between those who forge the tools of information theory and those who use them, the communications engineer must understand the mathematician's results and the mathematician must be apprised of the communications engineer's needs. As intermediaries, more applied mathematicians are needed who are versed in communications engineering and more communications engineers who are educated in the necessary mathematics. They are essential to serve as the channel of what should be an efficient 2-way communication system.

Analysis of Linear Sampled-Data Systems with Finite Pulse Width: Open Loop

G. FARMANFARMA
STUDENT MEMBER AIEE

Synopsis: An exact method for analysis of sampled-data systems with finite pulse width is presented. The results make it possible to obtain the output of such systems in a closed form, as a continuous function of time, and without recourse to any approximations. (The closed form is that which does not involve summation of series.) The analysis is based on introducing a new transform method, analogous to the z-transform, except that the actual pulse width and pulse shape are considered. This is called the p-transform where p denotes pulse width. Furthermore, by utilizing the modified z-transform, a method for obtaining the inverse Laplace transform of functions involving both ϵ^{Ts} and s is developed. This technique has been advantageously applied to evaluate the inverse p-transform in a closed form. (The term "modified z-transform" was introduced in reference 1.) The limiting cases of the p-transform are investigated. It is concluded that the p-transformation method provides a powerful technique for analysis of sampled-data systems with finite pulse width.

ANALYSIS and design of sampled-data control system have been the subject of considerable investigation in the last few years. The methods of analysis are based on: 1. Laplace transform and the use of impulse response,[2] 2. Laplace transform leading to the frequency response approach,[3] and 3. z-transform[4–6] and the modified z-transform.[1,7]

The impulse response is a logical application of the superposition principles. It is based on adding the effect of each successive pulse, either graphically or numerically. Basically it is a tool for analysis. It can give the continuous output and has the advantage that it is applicable to both the periodic and nonperiodic sampled-data systems. However, its scope of application is limited because of the labor involved.

The second method is based on the infinite series equivalent of the z-transform.[5,6] Theoretically, it can yield the continuous response. But in general the output is in the form of an infinite series, and hence it must be approximated. The degree of accuracy depends on the number of terms included and the rapidity with which the infinite series converges. The computational labor renders this method inferior to both the impulse response and the z-transform technique.

Development of the z-transform in recent years has made this a powerful tool for analysis. The z-transform has one serious shortcoming: it can yield the output only at the sampling instants $t=nT$. However, at present there are several methods for determining the response between sampling instants utilizing z-transform.[1,7–10] Among these the modified z-transform[1,7] is the most valuable.

The modified z-transform is an important tool in the analysis and synthesis of sampled-data systems. Its application to analysis makes it possible to obtain the output as a continuous function of time, leading to determination of important quantities such as the peak time, peak overshoot,[1] etc. Its recent extension to synthesis[11] has shown it to be useful in system design, enabling the designer to meet rigid specifications. The modified z-transform as a mathematical tool has

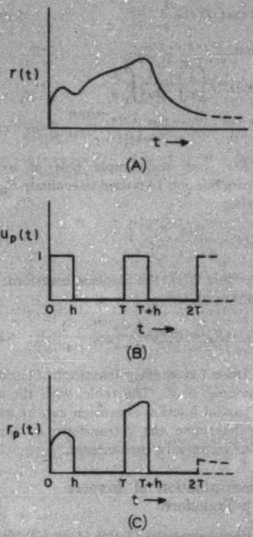

Fig. 2. A—Input signal to sampler. B—Unit pulse function. C—Sampler output constructed by multiplying input by unit pulse function

many applications outside the field of sampled-data control systems. Among these are its use in evaluating inverse Laplace transforms[13] (see the Appendix), and its application to design of continuous systems employing digital computers.[11]

The foregoing methods are all applicable to solution of sampled-data systems on the assumption of zero pulse width. Essentially the solutions are exact only if: 1. the sampler transforms the finite amplitude of input signal to true impulses of equivalent area (physically impossible), or 2. the sampler is followed by a hold circuit. (A hold circuit or boxcar generator is a circuit which maintains the output at the level of the sample until the new sample is taken.) Negligence to satisfy this fundamental requirement has led to some confusion in the past,[9] resulting in solutions which are known to be physically impossible.

It is known that with a finite pulse width, and in the absence of a hold circuit, the z-transform (or any of the foregoing methods) can be used to obtain an approximate solution.[4] This is based on the assumption that the pulse width is small compared to the time constants of the system. However, the degree of approximation has not been thoroughly investigated. Nor has there been a method for determining the response when the pulse width is comparable to the system time constants.

Investigating the effects of pulse width is of considerable importance in view of its engineering applications. For instance, a pulsed network in a servo loop might provide a desirable method of compensating the system. Also, techniques developed for the analysis of finite pulsed systems might eventually be applied to the analysis of relay servomechanism and other servo systems employing discontinuous elements such as biased magnetic amplifiers or vacuum-tube devices.

In this paper a new transform called the p-transform (p for pulse width) has been introduced for the exact analysis of finite pulsed linear systems. A general relation between the inverse Laplace transform and the inverse modified z-transform has been developed[13] (see the Appendix) and utilized to yield the inverse p-transform in a closed form. Tables of p-transform and inverse p-transform are given. With the aid of these tables it is possible to compute the output of a finite pulsed system as a continuous function of time. Numerical examples are worked to show the applications of these tables. The limiting cases of the p-transform have been investigated. It is shown that as the pulse width h approaches the sampling period T, the p-transform approaches the ordinary Laplace transform for the continuous system. This is an expected result and can serve as a valuable check in many problems. Furthermore, the extent of the error caused by the use of z-transform approximation and its validity are thoroughly investigated. Numerical example is worked to show the error that can be caused when the z-transform approximation is applied to systems having discontinuous impulse response.

The p-transform is a general tool for treatment of finite pulsed systems. It has been applied to solutions of feedback problems. However, much remains to be done before a complete report can be made. Hence, this paper is limited to the applications of the p-transform to solution of open-loop systems with a periodic sampler having uniform pulse width (i.e., all pulses are of the same width h).

Introduction to p-Transform

As it is often stated, the basic difference between continuous system and a finite pulsed sampled-data system is due to the presence of the sampler in the latter. Thus any general investigation of the pulsed system must start with the study of the sampler, and the relation between its input and output time functions. Fig. 1 illustrates an ideal sampler, ideal because it is assumed that it can make or break instantaneously. If the sampling equipment does not possess this ideal characteristic, then it must modify the signal according to some known function. It is clear that under these conditions the modifying function can

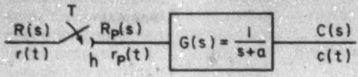

Fig. 4. Finite pulsed system

be represented by the corresponding block in the block diagram and its effect considered to be outside of the actual sampling process. Hence the task of determining the relation between input and output of the ideal sampler still remains. In the following, the relation between the Laplace transform of the input and output of a sampler is determined, assuming an ideal periodic sampler with period T and uniform pulse width h.

Let $r(t)$ in Fig. 2(A), be an arbitrary input to the sampler, then the corresponding output of an ideal periodic sampler is the time function $r_p(t)$, shown in Fig. 2(C). Inspection shows that it is possible to reconstruct $r_p(t)$ by multiplying the input $r(t)$ by a time function $u_p(t)$ as shown in Fig. 2(B) where

$$\begin{aligned} u_p(t)&=1 \qquad nT\leq t\leq nT+h \\ u_p(t)&=0 \qquad nT+h\leq t\leq (n+1)T \\ & \qquad\quad n=0,1,2,3\ldots \end{aligned} \tag{1}$$

Fig. 2 shows that when $r(t)$ is multiplied by the unit pulse function $u_p(t)$, the resultant is the time function $r_p(t)$ indicated in Fig. 2(C), which is identical to the sampler output. Thus, in effect, the sampler may be regarded as a multiplier in the time domain, multiplying its input by the unit pulse function $u_p(t)$. Hence, the relation between input and output in the time domain may be written as

$$r_p(t)=r(t)u_p(t) \tag{2}$$

where $r_p(t)$ is the sampler output. The Laplace transform of equation 2 is

$$\mathfrak{L}[r_p(t)]=\mathfrak{L}[r(t)u_p(t)] \tag{3}$$

Complex convolution[6,13] can be used to evaluate equation 2 as follows: Let

$$\mathfrak{L}[r_p(t)]=R_p(s) \tag{4}$$

$$\mathfrak{L}[r(t)]=R(s) \tag{5}$$

and

$$\mathfrak{L}[u_p(t)]=U_p(s)=\frac{1-\epsilon^{-hs}}{s(1-\epsilon^{-Ts})} \tag{6}$$

Then the Laplace transform of the output $R_p(s)$ may be expressed in terms of $R(s)$ and $U_p(s)$ as

$$R_p(s)=\frac{1}{2\pi j}\int_\Gamma R(v)U_p(s-v)dv \tag{7}$$

Substituting equation 6 in 7 results in

$$R_p(s)=\frac{1}{2\pi j}\int_\Gamma R(v)\frac{1-\epsilon^{-h(s-v)}}{(s-v)[1-\epsilon^{-T(s-v)}]}\,dv \tag{8}$$

where Γ is the contour of integration enclosing all the poles of $R(v)$ to its left,[6] shown in Fig. 3, and

$$R(v)=R(s)|_{s=v} \tag{9}$$

Equation 8 expresses the Laplace transform of the output in terms of the Laplace transform of input. Hence the sampler can be regarded as an operator in the s-plane transforming the input $R(s)$ according to equation 8 to give the output $Rp(s)$. For brevity this is called p-transformation and is denoted by

$$R_p(s)=\mathrm{P}[R(s)] \tag{10}$$

Its inverse is denoted by

$$r_p(t)=\mathrm{P}^{-1}[R_p(s)] \tag{11}$$

It is evident from the preceding equations that the p-transform is only a particular form of the Laplace transform. Thus all operations which are valid for Laplace transformations are identically valid for the p-transformation.

Equation 8 can be readily evaluated by the residue method. Assuming

$$R(s)=\frac{A(s)}{B(s)} \tag{12}$$

where $A(s)$ and $B(s)$ are polynomials in s, then $R_p(s)$, the Laplace transform of the sampler output, is given by

$$R_p(s)=\sum_{\substack{\text{roots of}\\ B(v)}}\text{residue of}\left[\frac{A(v)}{B(v)}\frac{1-\epsilon^{-h(s-v)}}{(s-v)[1-\epsilon^{-T(s-v)}]}\right]\text{ at the roots of } B(v) \tag{13}$$

A special case arises when $R(s)$ has simple poles only,[6,13] then equation 13 reduces to

$$R_p(s)=\sum_{n=1}^{N}\frac{A(v_n)}{B'(v_n)}\frac{1-\epsilon^{-h(s-v_n)}}{(s-v_n)[1-\epsilon^{-T(s-v_n)}]} \tag{14}$$

where

$$B'(v_n)=\left.\frac{dB(v)}{dv}\right|_{v=v_n} \tag{15}$$

and $v_1, v_2 \ldots v_N$ are the simple roots of $B(v)$. Equations 13 and 14 indicate that the p-transform of any function is composed of functions ϵ^{-hs}, ϵ^{-Ts}, and s. Once the transform of the sampler output is found, the usual continuous system procedure can be used to find the final response. To illustrate, consider the system shown in Fig. 4. Let the input be

$$r(t)=1 \text{ (unit step)} \tag{16}$$

$$\text{so that } R(s)=\frac{1}{s} \tag{17}$$

then

$$R_p(s)=\mathrm{P}\left[\frac{1}{s}\right]=\frac{1}{2\pi j}\int_\Gamma\frac{1}{v}\,\frac{1-\epsilon^{-h(s-v)}}{(s-v)[1-\epsilon^{-T(s-v)}]}\,dv \tag{18}$$

$R(v)$ has one simple pole at $v=0$. Hence relation 14 is used to evaluate $R_p(s)$ giving

$$R_p(s)=\frac{1-\epsilon^{-hs}}{s(1-\epsilon^{-Ts})} \tag{19}$$

therefore $C(s)$, the Laplace transform of the output, is

$$C(s)=R_p(s)\;G(s)=\frac{1-\epsilon^{-hs}}{1-\epsilon^{-Ts}}\;\frac{1}{s(s+a)} \tag{20}$$

Table I gives the p-transform of various functions of s. The table, with the aid of partial fraction expansion can be used to determine the p-transform of functions commonly encountered.

Determination of Inverse p-Transform

From equations 13 and 14, and Table I, it is evident that a term in the form of

$$\frac{1-\epsilon^{-h(s+b)}}{1-\epsilon^{-T(s+b)}} \tag{21}$$

is common to all p-transforms for the periodic case being considered. This function has an infinite number of simple poles at

$$s=-b\pm j\frac{2k\pi}{T} \qquad k=1,2,3\ldots \tag{22}$$

Because of these poles, attempts to use the inverse Laplace integral to obtain the time function leads to an infinite series. To avoid this, a relation between the inverse Laplace transform and the inverse modified z-transform has been developed and utilized to give the inverse p-transform in a closed form. Most common p-transforms and their inverses are shown in Table II. The relation between the inverse Laplace transform and the inverse modified z-transform, together with the technique for deriving the inverse p-transform are explained in the Appendix.

Although no knowledge of the modified z-transform is necessary for the use of Table II, a thorough understanding of the notations used is essential. The inverse p-transform is expressed as a function of t,n,m,T, and $d(-h)$, where $d(-h)$

$Kf(t)$ denotes a delay of h seconds along the positive time axis operating on the function $Kf(t)$. It is identical to the Laplace notation, $u(t-h)\,Kf(t-h)$; $d(-h)$ is used primarily as a shorthand notation, its meaning illustrated in Fig. 5. Thus

$$d(-h)f(t)=u(t-h)f(t-h) \tag{23}$$

The time t is related to n,m, and T by equation

$$t=(n-1+m)T \tag{24}$$

where

$t\geq 0$
T = period of sampler in seconds
$n=1, 2, 3 \ldots$
= number of sampling periods from zero time. (At $t=0$, n can be zero on condition $m=1$; see equation 24.)
m = a numerical variable of such a form that at all times $0\leq m\leq 1$

Since n is always an integer, then m must be chosen to satisfy relation 24 corresponding to the instant of time t. At the sampling instants in general, it does not matter whether the value $m=0$, or $m=1$ is chosen to satisfy equation 24, but if there are discontinuities in the inverse time function at these instances, then substitution of $m=0$ gives the upper limit and $m=1$ the lower limit. Mathematically this may be stated as

$$\lim_{m\to 0} c(t)\Big|_{t=(n-1+m)T}=c(n-1)T^{+} \tag{25A}$$

$$\lim_{m\to 1} c(t)\Big|_{t=(n-1+mT)}=c(n-1)T^{-} \tag{25B}$$

As t increases n also increases, in the steady state, all terms having ϵ^{-nT} and ϵ^{-t} as multipliers approach zero. Thus these terms form the transient components of the time functions. Inspection of Table II shows that in all cases the inverse time function is composed of a transient term plus a steady-state term. The steady-state condition is readily obtained by letting the terms multiplied by ϵ^{-nT} and ϵ^{-t} assume zero value.

To illustrate the procedure the inverse of equation 20, for the output of the system shown in Fig. 4 is calculated. The output time function $c(t)$ is given by

$$c(t)=\mathrm{P}^{-1}[R_p(s)G(s)]$$
$$=\mathrm{P}^{-1}\left[\frac{1-\epsilon^{-hs}}{1-\epsilon^{-Ts}}\,\frac{1}{s(s+a)}\right] \tag{26}$$

The form is similar to relation 5 of Table II with a_1 equated to zero. Let $a=1$, $T=0.5$ second. If these are substituted in relation 5 of Table II the inverse time function can be written as

$$c(t)=[1-d(-h)]\left\{n-\frac{1}{(\epsilon^{0.5}-1)}[\epsilon^{-0.5(m-1)}-\epsilon^{-t}]\right\} \tag{27}$$

Substituting

$$A=\frac{1}{\epsilon^{0.5}-1}\epsilon^{-0.5(m-1)} \tag{28}$$

$$B=\frac{1}{\epsilon^{0.5}-1}\epsilon^{-t} \tag{29}$$

the time function can be written as

$$c(t)=[1-d(-h)]\ (n-A+B) \tag{30}$$

Table III shows the procedure used for evaluating equation 30 for an assumed pulse width of $h=0.2$ second.

From equation 30 and Fig. 5 it is seen that, once the function $(n-A+B)$ is evaluated, a relative displacement and subtraction can yield the output for any value of pulse width h. This procedure is illustrated graphically in Fig. 6 for $h=0.35$ second and analytically in Table III for $h=0.2$ second. The time function $c(t)$ is plotted in Fig. 7 for various values of h including $h=T=0.5$, the continuous case. (See the section "Limiting Case of p-Transform.")

Other Uses of Inverse p-Transform

From the preceding discussion and examples it is clear that the p-transform is a special form of the Laplace transform. Hence it is evident that

$$r_p(t)=\mathrm{P}^{-1}[R_p(s)]_{t=(n-1+m)T}=\mathfrak{L}^{-1}[R_p(s)] \tag{31}$$

Despite this identity, the process of taking the inverses are markedly different.

$\mathrm{P}^{-1}[R_p(s)]$

denotes a completely different operation on $R_p(s)$ as compared to

$\mathfrak{L}^{-1}[R_p(s)]$

The final form of the time functions $r_p(t)$ also differs greatly in the two cases; they yield the same values only after numerical substitutions.

As pointed out previously (see the section "Determination of Inverse p-Transform") the inverse Laplace leads to an infinite series for the time function. Let this be written as

$$\mathfrak{L}^{-1}[R_p(s)]=x(t)+\text{infinite series in }(t) \tag{32}$$

where $x(t)$ is a closed time function (usually the transient component).

The inverse p-transform, on the other hand, results in a closed form of the time function, expressed in terms of t, n, m, and T. Let this be written as

$$\mathrm{P}^{-1}[R_p(s)]_{t=(n-1+m)T}=y(t)\Big|_{t=(n-1+m)T} \tag{33}$$

where $y(t)$ = transient part + steady-state component. But relation 31 shows equa-

Note: By substituting $n=1$, and $mT=t$ in any of these equations, it can be shown analytically that the inverse time function $f(t)$ simplifies to the inverse Laplace for the continuous system. This is expected since for $0\leq t\leq h$ the pulsed system response is identical to the continuous system response.

tions 32 and 33 to be equivalent; hence

$$y(t)\big|_{t=(n-1+m)T}=x(t)+\text{infinite series in }(t) \tag{34}$$

Therefore

$$\text{infinite series in }(t)=y(t)-x(t) \tag{35}$$

Equation 35 indicates that the inverse p-transform can be used to sum up infinite series; see the Appendix. Usually the infinite series part of equation 32 is the Fourier series expansion of the steady-state solution. This leads to the conclusion that the inverse p-transform can be used to find a closed sum for a periodic time function which can be expanded in a Fourier series. A simple example in the Appendix illustrates the applicability of equation 35.

The inverse p-transform has another useful application. This can be demonstrated by considering the following function

$$\frac{1-\epsilon^{-h(s+a)}}{1-\epsilon^{-T(s+q)}}G(s)$$

$$=\left[\frac{G(s)}{1-\epsilon^{-T(s+q)}}-\frac{\epsilon^{-ah}\epsilon^{-hs}G(s)}{1-\epsilon^{-T(s+q)}}\right] \tag{36}$$

The inverse p-transform of this can in general be written as

$$P^{-1}\left[\frac{1-e^{-h(s+a)}}{1-\epsilon^{-T(s+q)}}G(s)\right]$$

$$=[1-\epsilon^{-ah}d(-h)]f(t) \tag{37}$$

$$=[f(t)-\epsilon^{-ah}u(t-h)f(t-h)]$$

Then, clearly

$$P^{-1}\left[\frac{G(s)}{1-\epsilon^{-T(s+q)}}\right]=f(t)$$

$$=\mathcal{L}^{-1}\left[\frac{G(s)}{1-\epsilon^{-T(s+q)}}\right] \tag{38}$$

Thus, effectively, Table II can be considered to be an inverse Laplace table for the functions involving both ϵ^{Ts} and s. Hence Table II can be used to solve general problems arising in Laplace transformations quite independent of whether the sampler is present or not.

To illustrate, consider the effect of applying the periodic saw-toothed voltage of Fig. 8 to a series *R-L* (resistance-inductance) circuit. Assuming zero initial conditions, the relation between the Laplace transforms of the current and voltage may be written as

$$I(s)=\frac{E(s)}{L\left(s+\frac{R}{L}\right)} \tag{39}$$

where

$$I(s)=\mathcal{L}[i(t)] \tag{40}$$

$$E(s)=\mathcal{L}[e(t)]$$

$$=K\left[\frac{(1-\epsilon^{-hs})}{(1-\epsilon^{-Ts})s^2}-\frac{h\epsilon^{-hs}}{s(1-\epsilon^{-Ts})}\right] \tag{41}$$

Substituting equation 41 in equation 39, and simplifying, gives

$$I(s)=\frac{K}{R}\left[\frac{(1-\epsilon^{-hs})}{(1-\epsilon^{-Ts})}\frac{1}{s^2}-\frac{\left[1+\left(\frac{R}{L}h-1\right)\epsilon^{-hs}\right]}{(1-\epsilon^{-Ts})}\frac{1}{s\left(s+\frac{R}{L}\right)}\right] \tag{42}$$

Let

$$\left.\begin{aligned}&R=1\\&L=2\text{ henrys}\\&\frac{R}{L}=0.5\\&h=0.4\text{ second}\\&T=1\text{ second}\\&K=1\end{aligned}\right\} \tag{43}$$

From these and relations 8 and 5 of Table II, the inverse of equation 42 may be written as

$$i(t)=\left\{[1-d(-0.4)]\,n\frac{(m+t)}{2}-[1-0.8d(-0.4)]\left[\frac{n}{0.5}-\frac{1}{0.5(\epsilon^{0.5}-1)}(\epsilon^{-0.5(m-1)}-\epsilon^{-0.5t})\right]\right\} \tag{44}$$

Let

$$A=n\frac{(m+t)}{2} \tag{45}$$

$$B=\frac{n}{0.5}=2n \tag{46}$$

$$C=\frac{1}{0.5(\epsilon^{0.5}-1)}\epsilon^{-0.5(m-1)} \tag{47}$$

$$D=\frac{1}{0.5(\epsilon^{0.5}-1)}\epsilon^{-0.5t} \tag{48}$$

Then $i(t)$ may be written as

$$i(t)=\{[1-d(-0.4)]A-[1-0.8d(-0.4)](B-C+D)\} \tag{49}$$

Table IV shows the procedure used for evaluating equation 49. The resulting $i(t)$ is plotted in Fig. 9.

The foregoing example illustrates the use of Table II for solving problems involving periodic time functions. The advantages in the use of this table are that the solution is exact, avoiding tedious summation of infinite series terms.

Limiting Cases of p-Transform

The *p*-transform must satisfy certain known limiting conditions. It is interesting to study these limiting cases and compare the results with those physically expected.

There are four possible limits:

Case A: $h=0$ with $u_p(t)$ having any finite amplitude K, Fig. 10(A).

Case B: $h=0$ but $u_p(t)$ becomes unit impulses (i.e., has infinite amplitude and area = unity), Fig. 10(B).

Case C: $h=T$, $u_p(t)$ becomes unit step Fig. 10(C).

Case D: h is small compared to time constants of the system Fig. 10(D).

Case A

From Fig. 10(A): $h=0$, $u_p(t)$ has finite amplitude K. This is a trivial case. Under these conditions, the Laplace transform of the pulse function can be written as[14]

$$\mathcal{L}[u_p(t)]=\frac{\int_0^0 K\epsilon^{-st}\,dt}{1-\epsilon^{-Ts}}=0 \tag{50}$$

Thus the sampler output is zero, and the system remains at rest. This is to be expected since under these conditions the system does not receive any energy to cause a change.

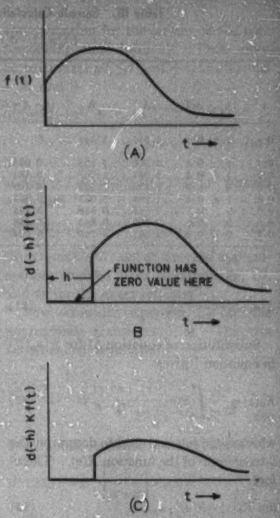

Fig. 5. Illustrating meaning of $d(-h)f(t)$

Case B

From Fig. 10(B): $h=0$, $u_p(t)$ becomes unit impulses (unit area). Then

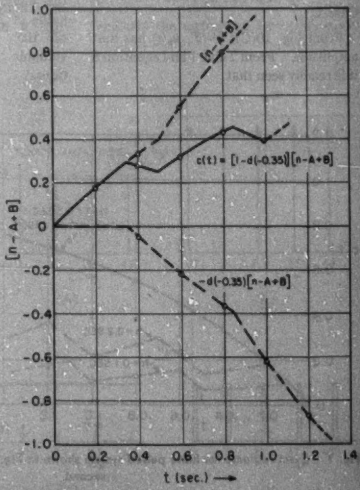

Fig. 6. Graphic method for evaluating output $c(t)$

Table III. Sample Calculation for Evaluating Equation 30

$c(t)=[1-d(-h)](n-A+B)$

t	n	mT	A	B	$(n-A+B)$	$d(-0.2)\times(n-A+B)$	$c(t)$ $h=0.2$	$c(t)$ $h=T=0.5$	$c(t)=\mathcal{L}^{-1}\left[\frac{1}{s(s+1)}\right]$
0	1	0	2.541	1.541	0	↑ $h=0.2$	0	0	0

0.7	2	0.2	2.081	0.765	0.684	0.394	0.290	0.503	0.503

$$\mathcal{L}[u_p(t)]=\frac{1}{1-\epsilon^{-Ts}} \tag{51}$$

Substitution of equation 51 for $\mathcal{L}[u_p(t)]$ in equation 7 gives

$$R_p(s)=\frac{1}{2\pi j}\int_\Gamma R(v)\frac{1}{1-\epsilon^{-T(s-v)}}\,dv \tag{52}$$

which is the relation used to determine the z-transform[6] of the function $R(v)$. Therefore

$$\lim_{\substack{h\to 0\\ K\to\infty\\ hK\to 1}} R_p(s)=R(z)\big|_{z=\epsilon^{sT}} \tag{53}$$

where K is the amplitude of $u_p(t)$.

This case occurs in problems where mathematically the behavior of the system can be formulated in terms of true impulses; see also case D. In such cases tables of z-transform,[6] modified z-transform[1,7] and their inverse, together with Table II, are suited for finding a solution.

Case C

From Fig. 10(C): $h=T$, $u_p(t)$ has unit amplitude. From Table I and equation 8 it is readily seen that

$$\lim_{h\to T} R_p(s)=R(s) \tag{54}$$

This is clearly an expected result. From equations 54 and 31 it follows that

$$\lim_{h\to T} \mathrm{P}^{-1}[R_p(s)]=\mathcal{L}^{-1}[R(s)] \tag{55}$$

This, although true, is not obvious from the inverse tables. This is because of the particular method used to evaluate the inverse p-transform. However, it is possible to show both analytically (see note in Table II) and numerically, that relation 55 is satisfied by any one of the p-transform pairs listed in Table II. For example, referring to Fig. 4, and from equations 20 and 30, it is to be expected that

$$c(t)=[1-d(-T)]\,(n-A+B)=\mathcal{L}^{-1}\left[\frac{1}{s(s+1)}\right] \tag{56}$$

Table III, together with Fig. 7, shows that this identity is satisfied for the assumed value of $T=0.5$ second. This property of the p-transformation provides a valuable check for numerical calculations.

Case D

From Fig. 10(D): h, small compared to the time constants of the system. This case can be best illustrated by means of an example: Consider the system shown in Fig. 4, with a single time constant $\tau=1/a$. The output is given by equation 20 as

$$C(s)=\frac{1-\epsilon^{-hs}}{(1-\epsilon^{-Ts})s}\,\frac{1}{(s+a)} \tag{20}$$

For $t\geq h$, the numerator can be expanded in powers of hs and assuming, for the time being, that h is sufficiently small so that (h^2s^2) and higher powers can be neglected then $C(s)$ may be closely approximated by

$$C_1(s)=\frac{h}{1-\epsilon^{-Ts}}\,\frac{1}{(s+a)}=\left[\frac{hz}{z-1}\,\frac{1}{(s+a)}\right]_{z=\epsilon^{sT}} \tag{57}$$

where $C_1(s)$ is an approximate transform. Equation 57 is the z-transform approximation used for solving such a system. Comparison of equations 20 and 57 shows that, effectively, the finite pulses in equation 20, with an area hK ($K=1$, unit step input) have been replaced by impulses of equal area, and then multiplied by system transfer function to obtain the approximate transform $C_1(s)$. It is the purpose of the following section to derive the inverse of equation 20 in order to compare it with the approximate inverse obtained from equation 57, and hence show the extent of the approximation caused by the use of equation 57.

For clarity it is advisable to divide the time axis into four regions, corresponding to the four operations of the sampler during each cycle. Let these be

1. $t=nT$, $n=0, 1, 2, 3 \ldots$, the actual sampling instants.
2. $nT<t<nT+h$, the time during which the sampler is definitely closed.
3. $t=nT+h$, the actual instants at which the sampler is transferred from closed to open position.
4. $nT+h<t<(n+1)T$, the time during which the sampler is definitely open.

Regions 1 and 3 are the boundary points.

2.4	3	0.4	4.2	3.0	1.2	6	4.162	0.929	2.767	1.641	1.126	0.074

Equation 20 for the exact transform of the output may be written as

$$C(s)=\frac{1-\epsilon^{-hs}}{s(s+a)}\,[1+\epsilon^{-Ts}+\epsilon^{-2Ts}+\ldots] \quad (58)$$

Let

$$\mathcal{L}^{-1}[R(s)G(s)]=\mathcal{L}^{-1}\left[\frac{1}{s(s+a)}\right]$$
$$=f(t)=\frac{1}{a}\,(1-\epsilon^{-at}) \quad (59)$$

From these the inverse time function can be evaluated term by term as

$$c(t)=\frac{1}{a}\,(1-\epsilon^{-at}) \text{ for } 0\leq t\leq h \quad (60)$$

$$c(t)=\frac{1}{a}\,(\epsilon^{ah}-1)\epsilon^{-at} \text{ for } h\leq t\leq T \quad (61)$$

These may be generalized as follows for $nT\leq t\leq nT+h$ i.e., regions 1, 2, and 3.

$$c(t)=\left\{\left(\frac{\epsilon^{ah}-1}{a}\right)[1+\epsilon^{aT}+\epsilon^{2aT}+\ldots+\epsilon^{(n-1)aT}]\epsilon^{-at}+\frac{1}{a}[1-\epsilon^{-a(t-nT)}]\right\} \quad (62)$$

and for $nT+h\leq t\leq(n+1)T$, i.e., regions 3, 4, and 1.

$$c(t)=\frac{\epsilon^{ah}-1}{a}\,[1+\epsilon^{aT}+\epsilon^{2aT}+\ldots+\epsilon^{anT}]\epsilon^{-at} \quad (63)$$

The output at the sampling instants $t=nT$ can be obtained from equation 62 and is

$$c(nT)=\frac{\epsilon^{ah}-1}{a}\,[\epsilon^{-aT}+\epsilon^{-2aT}:\ldots+\epsilon^{-anT}]+f(0) \quad (64)$$

where

$$f(0)=f(t)\big|_{t=0}$$

(see equation 59.) Equation 64 gives the true output at the sampling instants $t=nT$, since it is derived from the exact transform. When the ratio $ah=h/\tau$, where τ=time constant, is small so that (a^2h^2) and higher powers can be neglected, then $\epsilon^{ah}-1/a$ can be closely approximated by

$$\frac{\epsilon^{ah}-1}{a}\simeq h \quad (65)$$

Substituting equation 65 in 64, a true approximation for the output at times $t=nT$ is obtained. This is

$$c_a(nT)=h[\epsilon^{-aT}+\epsilon^{-2aT}+\ldots+\epsilon^{-anT}]+f(0) \quad (66)$$

Similarly, substitution of relation 65 in equations 62 and 63 results in a true approximation for the output at the corresponding time intervals. These may be written for $nT\leq t\leq nT+h$, i.e., regions 1, 2, and 3

$$c_a(t)=h[1+\epsilon^{aT}+\ldots+\epsilon^{(n-1)aT}]\epsilon^{-at}+\frac{1}{a}[a-\epsilon^{-a(t-nT)}] \quad (67)$$

and for $(nT+h)\leq t\leq(n+1)T$, i.e., regions 3, 4, and 1

$$c_a(t)=h[1+\epsilon^{aT}+\epsilon^{2aT}+\ldots+\epsilon^{anT}]\epsilon^{-at} \quad (68)$$

Equations 66, 67, and 68 are valid approximations derived from equations 62, 63, and 64 for the exact response.

Now, consider equation 57 for the approximate transform $C_1(s)$. This can be expanded as follows

$$C_1(s)=\frac{1}{(s+a)}\,[1+\epsilon^{-Ts}+\epsilon^{-2Ts}+\ldots+\epsilon^{-nTs}+\ldots] \quad (69)$$

The impulse response of the system is

$$\mathcal{L}^{-1}[G(s)]=\mathcal{L}^{-1}\left[\frac{1}{s+a}\right]=g(t)=\epsilon^{-at} \quad (70)$$

Thus the inverse transform of equation 69 representing the approximate inverse time function is

$$c_1(t)=h[1+u(t-T)+u(t-2T)+\ldots]\epsilon^{-at} \quad (71)$$

From this the output at the sampling instants $t=nT$ may be written as

$$c_1(nT)=h[g(0)+\epsilon^{-aT}+\epsilon^{-2aT}+\ldots+\epsilon^{-anT}] \quad (72)$$

where

$g(0)=g(t)\big|_{t=0}=1$ (in this case)

Similarly the output at any other time

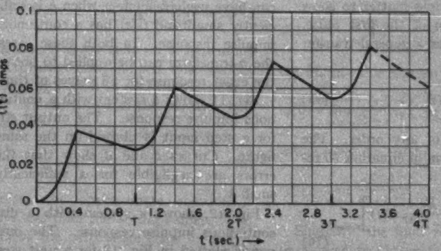

Fig. 9 (above). Plot of current i(t) in the series R/L circuit for the applied saw-toothed voltage

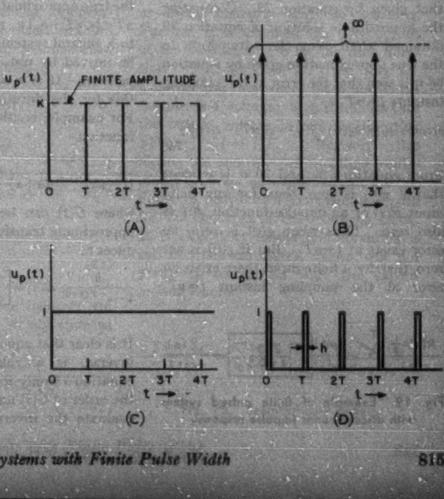

Fig. 10 (right). Limiting cases of pulse function $u_p(t)$

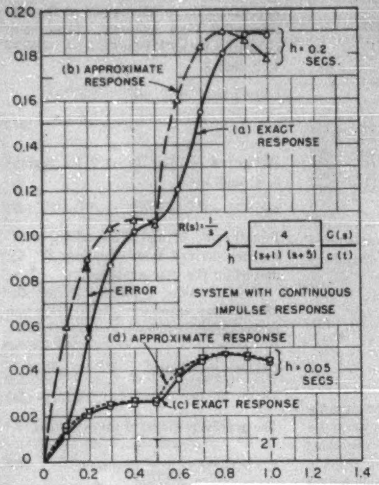

Fig. 11. Response of system with continuous impulse response. Plot shows that errors are small for sufficiently small h

$nT<t<(n+1)T$, i.e., regions 2, 3, and 4 can be written as

$$c_1(t)=h[1+\epsilon^{aT}+\epsilon^{2aT}+\ldots+\epsilon^{anT}]\epsilon^{-at} \tag{73}$$

Equations 72 and 73 are the resulting time functions when equation 20 is approximated by equation 57.

It is known that z-transform can only give information at sampling instants $t=nT$. Hence, if the z-transform is applied to equation 57 to evaluate the response of the system at these instants, the result obtained will be identical to that given by equation 72. Comparing the approximate solution of equation 72 obtained when using the z-transform to the true approximation given by equation 66 it is seen that the error at the sampling instants $t=nT$ is

$$\text{error}\Big|_{t=nt}=hg(0)-f(0)=c_1(nT)-c_2(nT) \tag{74}$$

From equations 59 and 70 it is evident that if $g(0)$ is zero, then for any finite input $R(s)$ or an impulse function, $f(0)$ is also zero. Thus when $g(0)$ is zero, no error exists at $t=nT$. But if $g(0)$ is not zero, then for a finite input there exists an error at the sampling instant $t=nT$.

Fig. 12. Example of finite pulsed system with discontinuous impulse response

Hence it can be stated that the use of z-transform (equation 57) for determining the solution of finitely pulsed system at sampling instants, $t=nT$ is not correct, leading to wrong results, unless the system transfer function $G(s)$ has a continuous impulse response, i.e., the degree of its denominator in s is two or more higher than the degree of its numerator.

Comparison of equation 73 with equations 67 and 68 also shows that the time domain solution derived from the approximate transform does not correspond with the true approximation during the interval $nT<t<nT+h$, i.e., region 2. This applies to a general system of any order and can be proved by use of partial fraction expansion. It is a simple matter to show this for the duration of the first pulse. For example, consider a general transfer function

$$\frac{1-\epsilon^{-h(s+a)}}{[1-\epsilon^{-T(s+a)}](s+a)}G(s) \tag{75}$$

where $G(s)$ can be of any order. The approximate transform of equation 75 reduces to

$$\frac{h}{1-\epsilon^{-T(s+a)}}G(s)=\left[\frac{hz}{z-\epsilon^{-aT}}G(s)\right]_{z=\epsilon^{sT}} \tag{76}$$

It is clear that equation 76 (and hence its inverse) is a valid approximation of equation 75 only for $t\geq h$, irrespective of the order of $G(s)$ and the method used to evaluate the inverse. From these considerations a statement can be formulated as follows:

Consider a system with transfer function $G(s)$, the input to which is a sequence of finite pulses of width h and period T. When h is small compared to the time constants of the systems, the output can be approximated by replacing the finite pulses by impulses of equivalent area. In general two cases arise.

Case A: $G(s)$ has discontinuous impulse response. In this case, the solution is a true approximation for the time duration $nT+h\leq t<(n+1)T$, i.e., regions 3 and 4. This does not include the sampling instants $t=nT$. Hence the z-transform approximation completely fails in this case.

However, the modified z-transform can be used to obtain the output over the duration $nT+h\leq t<(n+1)T$. And by a limiting process at $(n+1)T$. (The modified z-transform gives results between sampling instants as well as the sampling instants. At a discontinuity it is possible to obtain both the upper and lower limits.)

Case B: $G(s)$ has continuous impulse response. In this case the approximate solution is valid for the time duration $nT+h\leq t\leq(n+1)T$, i.e., regions 3, 4, and 1. This includes the sampling instants $t=nT$. Here, both the z-transform and modified z-transform can be used to obtain a true approximate solution.

From these it is seen that the solutions derived from the approximate transforms, equations 57 and 76, are not a true approximation of the system output during the interval $nT<t<nT+h$, i.e., region 2, irrespective of the order of $G(s)$ and the method used to evaluate the inverse. This means that when the z-transform approximation is used, the true behavior of the system during the interval $nT<t<nT+h$ is not known. This, however, can have negligible effect when h is sufficiently small and $G(s)$ has a continuous impulse response. In both these cases, the p-transform can be applied to obtain the exact response for all values of time.

Fig. 11 shows a system with a continuous impulse response. The output $c(t)$ for a step input is plotted on the same figure. Curves c and d show that the errors are negligible for a sufficiently small h.

Fig. 12, shows a system with a discontinuous impulse response. The output is plotted in Fig. 13 for a unit step input, and assumed values of $h=0.2$ second and T=0.5 second. Curve a is the exact time function calculated from the inverse p-transform. Curve b is the approximate response calculated from the

Vol. 7
Pt. 1
1956

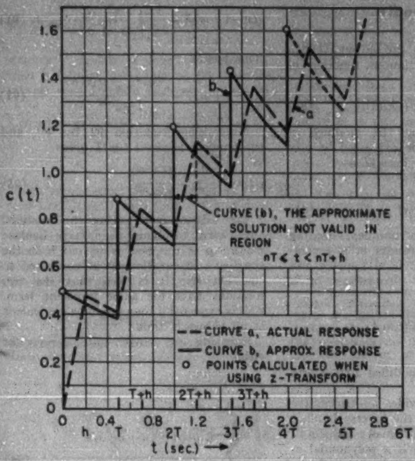

Fig. 13. Response of system shown in Fig. 12 to step input

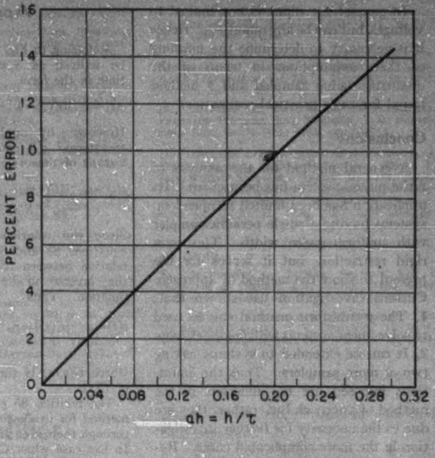

Fig. 14. Percentage error as function of ah for single time constant system

approximate transform. Comparison of the two curves shows the extent of the error which can be caused both at the sampling instants, and for the duration $nT<t<nT+h$ where the approximate transform is not valid.

In the foregoing the degree of approximation depends on the ratio of h to the time constants of the system. From equations 63, 65, and 68 it is seen that for the single time constant system of Fig. 4, with unit step input the approximations are due to substitution of

$$\frac{\epsilon^{ah}-1}{a}=h \qquad (65)$$

From this the percentage error can be expressed as

$$\text{per cent of error}=\left[1-\frac{ah}{\epsilon^{ah}-1}\right]\times 100 \qquad (77)$$

Equation 77 shows that for a step input the percentage error is fixed, independent of sampling period T, and time t. For a stable system (poles in the negative half of s-plane)

$$\frac{\epsilon^{ah}-1}{a}>h \qquad (78)$$

therefore the approximate solution is always less than the actual values. Fig. 14 shows the percentage error for a system with single time constant $\tau=1/a$ as a function of ah. It is seen that for an error of less than five per cent, ah must be less than or equal to one-tenth. For systems with more than one time constant the total error varies with time, as shown in Fig. 11.

Fig. 12 shows a single time constant system with $\tau=2$ seconds. Its output is plotted in Fig. 13 assuming a pulse width $h=0.2$, $T=0.5$, and a unit step input. Inspection shows that in its region of validity $(nT+h\leq t<(n+1)T)$ the approximate solution is less than the actual output, and the percentage error is nearly 5 per cent corresponding to $ah={}^1/_{10}$.

Initial and Final Values

Since p-transform is only a particular form of the Laplace transform, all operations valid for the Laplace transformation are equally applicable to p-transforms. For example, given a function

$$C_p(s)=\frac{1-\epsilon^{-h(s+a)}}{[1-\epsilon^{-T(s+a)}](s+a)}G(s) \qquad (79)$$

the initial value is given by

$$c_p(0)=\lim_{s\to\infty}\frac{s[1-\epsilon^{-h(s+a)}]}{[1-\epsilon^{-T(s+a)}](s+a)}G(s) \qquad (80)$$

which is equivalent to

$$c_p(0)=\lim_{s\to\infty}\frac{sG(s)}{(s+a)} \qquad (81)$$

Similarly, the final value theorem can be applied to obtain the steady state as the following

$$\lim_{t\to\infty}c_p(t)=\lim_{s\to 0}\frac{s[1-\epsilon^{-h(s+a)}]}{[1-\epsilon^{-T(s+a)}](s+a)}G(s) \qquad (82)$$

However, in most open loop cases, the final steady state is oscillating (see Fig. 7), hence the final value theorem is not applicable.

Practical Realization of Sampler

To correlate the theoretical calculations with practical results it is necessary that elements of the system be closely approximated by their idealized mathematical descriptions.

In the preceding discussions an ideal sampler has been assumed. That is, it is assumed that the sampler can make or break instantly with no sparking. Further, it is assumed that the output of the sampler is zero for the time duration $nT+h\leq t\leq(n+1)T$; see Fig. 2. Consider the case where the input to the sampler is a voltage; then it follows that the output voltage is zero for duration $nT+h\leq t\leq(n+1)T$. Effectively, this means the sampler (or sampling equipment) must act as a short circuit for this duration, providing a short-circuited path for the elements of the following block. It is clear that unless this condition is satisfied the calculated values will not prove to correspond with the experimental results.

Fig. 15. Sampled-data system

In general the input is not limited to voltages, but can be any quantity. Hence it is necessary to determine the meaning of these assumptions in terms of the quantities being sampled and a method found for their practical realization.

Conclusions

A general method for the analysis of finite pulsed system has been given. Its application has been limited to open-loop systems having a single periodic sampler with uniform pulse width. This is a rigid restriction, but it serves for the present to show the method of approach. Current investigation has shown that: 1. The p-transform method can be used to solve linear systems with feedback loop. 2. It can be extended to systems having two or more samplers. Thus the limitations imposed are not inherent in the method of approach but, rather, they are due to the necessity for further investigation in the more complicated cases. Results of these studies will be published in the near future.

In this paper it has been shown that:

1. The inverse p-transform table can be used to obtain the exact inverse Laplace of functions involving both ϵ^{Ts} and s.
2. Since the Laplace transform of periodic time functions are in the form of $F(s)/(1\mp\epsilon^{-Ts})$, then Table II can be used to obtain the inverse time function. However, any periodic time function has a Fourier series expansion in the time domain. Hence the inverse p-transform table can be used to find a closed form for the infinite series Fourier expansion.
3. It is shown that for a finite input and in the absence of a hold circuit, the z-transform leads to erroneous results unless the system transfer function has a continuous impulse response.
4. Application of p-transform results in the correct response irrespective of the form of the system impulse response. This includes systems whose transfer function have the same order polynomial in the numerator and denominator.
5. When the system transfer function has a continuous impulse response and the pulse width h is small, i.e., it is approximately equal to one tenth to one fifth of the smallest time constant of the system, then the z-transform technique can be used in order to obtain a reasonably approximate solution.
6. When the z-transform approximation is used, the true behavior of the system is not known during the interval in which the sampler is definitely closed.
7. When the input to the system consists of true impulses, or the system has a hold circuit, both the z-transform and the p-transform can be used to obtain the correct solution, independent of the system impulse response, on condition that the actual transfer functions allowing for the existing pulse width are considered.

Appendix

Referring to Fig. 15, the output $c(t)$ can be written as a continuous function of time in the form

$$c(t)=\mathcal{L}^{-1}[C(s)=\mathcal{L}^{-1}[R^*(s)G(s)] \qquad (83)$$

However, by applying the modified z-transform,[1] $c(t)$ can be expressed at any instant of time $t=(n-1+m)T$ as

$$\begin{aligned}c(t)&=z_m{}^{-1}[C(z,m)]\\&=z_m{}^{-1}[R(z)G(z,m)]_{t=(n-1+m)T} \qquad (84)\end{aligned}$$

Since the solution is unique, equating equations 83 and 84 results in a general relation between the inverse Laplace and the inverse modified z-transform of a function. Thus

$$c(t)=\mathcal{L}^{-1}[C(s)]=z_m{}^{-1}[C(z,m)]_{t=(n-1+m)T} \qquad (85)$$

where $C(z,m)$ is the modified z-transform of $C(s)$.

The relation 85 provides an alternative method for evaluating the inverse Laplace through the use of the modified z-transform. In the case when $C(s)$ is a polynomial in s, it is simpler to use the ordinary methods, and evaluate $c(t)$ directly from $C(s)$. But in cases when $C(s)$ is the Laplace transform of a periodic function, i.e., when it is of the form

$$\frac{1}{1\mp\epsilon^{-Ts}}F(s)$$

or has factorable terms in the form of

$$\epsilon^{+Ts}$$

then it becomes advantageous to obtain the inverse time function through the use of the modified z-transform. To illustrate consider the example

$$C(s)=\frac{1}{1-\epsilon^{-Ts}}\,\frac{1}{(s+a)} \qquad (86)$$

the inverse Laplace of this can be written as

$$c(t)=\frac{1}{2\pi j}\int_{c-j\infty}^{c+j\infty}\frac{\epsilon^{st}}{(1-\epsilon^{-Ts})(s+a)}\,ds \qquad (87)$$

the integrand has simple poles at $s=-a$ and $s=\pm j2k\pi/T$, $k=0, 1, 2, \ldots$ evaluating the integral at these simple poles gives

$$c(t)=\frac{\epsilon^{-at}}{1-\epsilon^{aT}}+\frac{1}{aT}+\frac{2}{T}\times\sum_{k=1}^{\infty}\frac{a\cos\frac{2\pi k}{T}t+\frac{2\pi k}{T}\sin\frac{2\pi k}{T}t}{a^2+\left(\frac{2\pi k}{T}\right)^2} \qquad (88)$$

Utilizing relation 85, the inverse time function may also be written as

$$c(t)=\mathcal{L}^{-1}[C(s)]=z_m{}^{-1}[C(z,m)]_{t=(n-1+m)T} \qquad (89)$$

where $C(z,m)$ is the modified z-transform of $C(s)$, and is

$$C(z,m)=\frac{z}{z-1}\,\frac{\epsilon^{-amT}}{z-\epsilon^{-aT}} \qquad (90)$$

The inverse of this is given by[1]

$$c(n-1+m)T=\frac{1}{2\pi j}\int_{\Gamma}\frac{z^n}{z-1}\,\frac{\epsilon^{-amT}}{z-\epsilon^{-aT}}\,dz \qquad (91)$$

This yields

$$c(n-1+m)T=\frac{\epsilon^{-amT}-\epsilon^{-aT(n+m)}}{1-\epsilon^{-aT}} \qquad (92)$$

Multiplying equation 92 by ϵ^{aT} and substituting $t=(n-1+m)T$ gives

$$c(t)=\frac{\epsilon^{-at}}{1-\epsilon^{aT}}-\frac{\epsilon^{aT(1-m)}}{1-\epsilon^{aT}} \qquad (93)$$

The advantage of using the modified z-transform to obtain the inverse Laplace transform in this case is evident from the simplicity of equation 93 as compared to equation 88. It is seen that the two solutions have the same transient term. This is expected if they are to be equivalent at all values of time.

Equating the steady-state component yields

$$\frac{\epsilon^{aT(1-m)}}{\epsilon^{aT}-1}=\frac{1}{aT}+\frac{2}{T}\times\sum_{k=1}^{\infty}\frac{a\cos\frac{2\pi k}{T}t+\frac{2\pi k}{T}\sin\frac{2\pi k}{T}t}{a^2+\left(\frac{2\pi k}{T}\right)^2} \qquad (94)$$

from which, by substitution of $t=(n-1+m)T$ is obtained the relation

$$\sum_{k=1}^{\infty}\frac{a\cos 2\pi km+\frac{2\pi k}{T}\sin 2\pi km}{a^2+\left(\frac{2\pi k}{T}\right)^2}=\frac{T[\epsilon^{aT(1-m)}]}{2(\epsilon^{aT}-1)}-\frac{1}{2a} \qquad (95)$$

$$0<m<1$$

Equation 95 is a by-product of the relation 85. The right-hand side is the closed form of the infinite series on the left-hand side. This identity has been checked and found to be correct for various values of a, T, and m.

In general, if $C(s)$ is the Laplace transform of a periodic function, the inverse Laplace is always in the form of an infinite series, but the use of relation 85 enables one to find a closed form for this infinite series, thus there is no reason why $C(s)$ should not be synthesized to give an infinite series whose sum is to be found in the time domain, and then the modified z-transform applied to get this sum.

Equation 93 shows that the inverse time function $c(t)$ can be written as

$$c(t)=\mathcal{L}^{-1}\left[\frac{1}{1-\epsilon^{-Ts}}\,\frac{1}{s+a}\right]=\frac{1}{\epsilon^{aT}-1}[\epsilon^{aT(1-m)}-\epsilon^{-at}] \qquad (96)$$

This identity can be used to evaluate the inverse p-transform of certain functions in a closed form. To illustrate, consider relation 4 of Table II. Let $q=0$, then $F_p(s)$ becomes

$$F_p(s)=\frac{1-k\epsilon^{-hs}}{1-\epsilon^{-Ts}}\,\frac{a_0}{(s+\gamma)} \qquad (97)$$

This may be written as

$$F_p(s) = [1 - k\epsilon^{-hs}]\left[\frac{1}{1-\epsilon^{-Ts}}\,\frac{a_0}{(s+\gamma)}\right] \quad (98)$$

since ϵ^{-hs} denotes a delay of h seconds, then it follows from equation 96 that the inverse time function $f_p(t)$ can be written

$$f_p(t) = [1 - kd(-h)]\left\{\frac{a_0}{\epsilon^{\gamma T}-1}[\epsilon^{\gamma T(1-m)} - \epsilon^{-\gamma t}]\right\} \quad (99)$$

which is the same as that listed in relation 4 of Table II with $q=0$. It is evident from the preceding that the inverse p-transform of other functions can be evaluated in a similar way. Thus, relation 85 can be advantageously applied to obtain the inverse p-transform in a closed form.

The Series Magnetic Amplifier

Part I—The Four Modes of Operation; Part II—The Mechanisms of Gain and Time Constant

R. C. BARKER
ASSOCIATE MEMBER AIEE

THE THEORETICAL writings of Storm[1-3] on magnetic amplifiers have deservedly received much attention. The references given to his work cite particularly his theory of the series-connected saturable reactor, to be called here the "series amplifier." It is assumed in the following that the reader is familiar with Storm's analysis of the series amplifier with comparatively low and comparatively high control-circuit resistance.

Two questions commonly arise regarding the solutions for extreme values of control resistance. One is "Why should the method of analysis depend upon the value of the control resistance?" and the other, "How does the control voltage 'control' the circuit?" If a generalized analysis were made, without assigning values to the control voltage and control resistance, one set of solutions would result which would apply for extreme and intermediate values of the control-circuit parameters as well.

Part I of this paper presents such a generalized analysis for the steady-state operation of the amplifier. The control voltage and resistance appear as parameters in the solutions. Two kinds of control voltages are considered: the direct voltage and the rectified sine wave. It is shown that the natural classification of amplifier operation is by modes defined by sequences of saturation states of the cores. The problem is to find the restrictions on circuit parameters and the control voltage for the existence of any given mode.

Perhaps the most important fact to note in Part I is that all the solutions are taken from one equation. The solutions for the four modes require some algebraic manipulations. But the only real theory involved is contained in a well-known average-flux theorem and a symmetry theorem, and the simple equation they imply. Part II shows that this one equation also contains a powerful physical picture of the mechanisms of gain and time constant.

Series Amplifier with D-C Control Voltage

In the following analysis, amplifier operation is divided into four distinct modes. These modes are distinguished by sequences of saturation states which occur within a cycle of the supply voltage. There are four of these saturation states: 1. neither core saturated, 2. core a saturated, 3. core b saturated, and 4. both cores saturated.

In each of the four saturation states, the circuit is represented by two linear voltage equations. Solutions for the circuit voltages, currents, and fluxes are easily obtained in each of the four saturation states. Within a given cycle, a succession of saturation states may exist, each for a finite angular interval. The problem remaining is to join these intervals to form a sequence of saturation states to meet certain requirements of symmetry and flux variation for the steady state.

CIRCUIT EQUATIONS FOR THE FOUR SATURATION STATES

The circuit to be considered is that of Fig. 1. The piecewise linear magnetic characteristics of Fig. 2 are assumed to apply. All windings are assumed to be resistanceless. The source of control signal is a direct voltage with an internal resistance R_c as shown in Fig. 1. The circuit consists of two electrical meshes coupled together by the two saturable reactors, core a and core b. Consequently, there are two voltage equations and two magnetic equations which can be written for the circuit. The special constraints dictated by a particular saturation

The original work was done under the sponsorship of the Wright Air Development Center. The project scientist was Dr. Rolf M. Wundt. Special acknowledgment is due Prof. Albert G. Conrad and Prof. Walter J. Cunningham for their advice in the performance of this research.

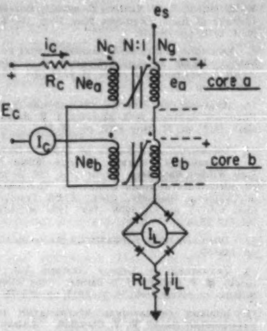

Fig. 1. Series magnetic amplifier

state can be introduced, and the solutions for the equations can be simply obtained for that state.

The voltage equations for the load and control sides of the amplifier are

$$e_s = e_a + e_b + i_L R_L \tag{1}$$

$$E_c = Ne_a - Ne_b + i_c R_c \tag{2}$$

The magnetic equations are written by referring to the assumed magnetic characteristics of Fig. 2

$$F_a = N_c i_c + N_g i_L \tag{3}$$

$$F_b = -N_c i_c + N_g i_L \tag{4}$$

For neither core saturated, the special constraints are

$$F_a = F_b = 0 \tag{5}$$

Equations 1 and 2 then become

$$e_s = e_a + e_b \qquad E_c = Ne_a - Ne_b$$

The desired solutions for the voltages and currents are obtained by applying the constraints of equation 5 to equations 1, 2, 3, and 4.

$$i_L = i_c = 0 \tag{6}$$

$$e_a = \frac{e_s}{2} + \frac{E_c}{2N} \tag{7}$$

$$e_b = \frac{e_s}{2} - \frac{E_c}{2N} \tag{8}$$

For core *a* saturated, the special constraints are

$$e_a = 0 \tag{9}$$

$$F_b = 0 \tag{10}$$

These constraints are first applied to equations 1 through 4. Equation 2 is then divided by *N* and added to equation 1.

$$e_s + \frac{E_c}{N} = i_L\left(R_L + \frac{R_c}{N^2}\right) \tag{11}$$

This equation brings into evidence the equivalent generator in the load circuit and the equivalent resistance through which the load current flows. This equivalent resistance is defined as

$$R_L' = R_L + \frac{R_c}{N^2} \tag{12}$$

The desired solutions for voltages and currents in the second saturation state then become

$$i_L = \left(e_s + \frac{E_c}{N}\right)\frac{1}{R_L'} \tag{13}$$

$$i_c = \left(e_s + \frac{E_c}{N}\right)\frac{1}{NR_L'} \tag{14}$$

$$e_b = e_s\left(1 - \frac{R_L}{R_L'}\right) - \frac{E_c}{N}\,\frac{R_L}{R_L'} \tag{15}$$

For core *b* saturated, the special constraints are

$$e_b = 0 \tag{16}$$

$$F_a = 0 \tag{17}$$

If one follows a procedure similar to that for state 2, the desired solutions for voltages and currents in the third saturation state become

$$i_L = \left(e_s - \frac{E_c}{N}\right)\frac{1}{R_L'} \tag{18}$$

$$i_c = -\left(e_s - \frac{E_c}{N}\right)\frac{1}{NR_L'} \tag{19}$$

$$e_a = e_s\left(1 - \frac{R_L}{R_L'}\right) + \frac{E_c}{N}\,\frac{R_L}{R_L'} \tag{20}$$

For both cores saturated, the special constraints are

$$e_a = 0 \tag{21}$$

$$e_b = 0 \tag{22}$$

The solutions for the currents become

$$i_L = \frac{e_s}{R_L} \tag{23}$$

$$i_c = \frac{E_c}{R_c} \tag{24}$$

Equivalent circuits for the four saturation states are shown in Fig. 3.

The solutions for the reactor voltages and currents in the four saturation states are only partial solutions, i.e., the solutions for one state are valid only for the angular interval corresponding to that state. The difficult part of finding the total solutions of the circuit equations is determining the states which appear in sequence and the order in which they occur. A sequence can be assumed, and the equation defining the steady state can be written. Over the range of parameters for which the solution of this equation exists, the assumed sequence is correct. For a given sequence, or mode, the average-flux and symmetry theorems[4] give the integral equation which can be solved for the firing angle as a function of the control voltage. These theorems are briefly stated in the following.

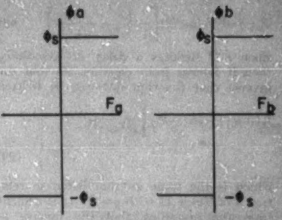

Fig. 2. Assumed magnetic characteristics

Average-flux theorem as it applies to this problem can be stated as follows: In the steady state, the net flux change in each core over any interval equal to the period of the supply frequency is zero. In concise form

$$\int_{\omega t}^{\omega t+2\pi} e_a d\lambda = \int_{t\omega}^{\omega t+2\pi} e_b d\lambda = 0 \tag{25}$$

The symbol λ is a general angular variable of integration.

The symmetry theorem for this circuit in the steady state is

$$e_a(\omega t) = -e_b(\omega t + \pi) \tag{26A}$$

$$e_b(\omega t) = -e_a(\omega t + \pi) \tag{26B}$$

The second integral of equation 25 can be written

$$\int_{\omega t}^{\omega t+\pi} e_b d\lambda + \int_{\omega t+\pi}^{\omega t+2\pi} e_b d\lambda = 0 \tag{27}$$

Equation 26(A) can be substituted into equation 27 with the result for the steady state

$$\int_{\omega t}^{\omega t+\pi} (e_a - e_b) d\lambda = 0 \tag{28}$$

All of the solutions for steady-state firing angle are found by performing the foregoing integration.

THE FOUR MODES OF CIRCUIT OPERATION

The first step in developing the four modes of circuit operation is to assume the sequence of saturation states that was found to exist in the simplified analysis of Storm. In this analysis it was found that twice per cycle state 1 appeared, alternating with intervals of state 2 and state 3. This sequence defines mode I. To illustrate the manner in which the sequence of saturation states defines the mode of operation, the four modes are summarized in Fig. 4.

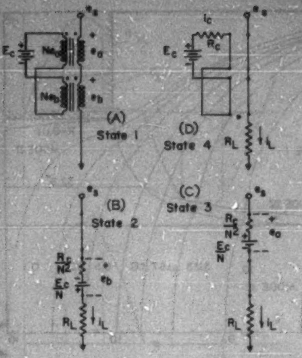

Fig. 3 (left). Equivalent circuits for four saturation states

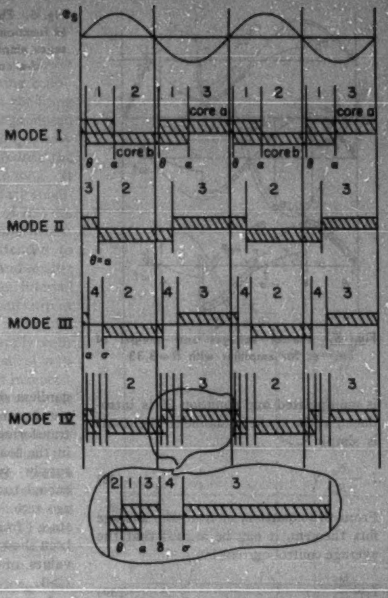

Fig. 4. Sequences of saturation states defining the four modes. Bars below and above axes indicate intervals in which core b and core a are unsaturated. Saturation states for intervals shown are numbered

Mode I

Suppose that core *b* is saturated. The magnetomotive force on core *b* is given by equations 4, 18, and 19.

$$F_b=N_g i_L-N_c i_c=\frac{2N_g}{R_L'}\left(e_s-\frac{E_c}{N}\right)=2N_g i_L \qquad (29)$$

Core *b* will return to its unsaturated condition when the magnetomotive force on the core becomes zero. Equation 29 shows that core *b* returns to its unsaturated condition when both the load current and control current become zero. This occurs when

$$e_s=\frac{E_c}{N} \qquad (30)$$

The supply voltage is negative during the half-cycle when core *b* is saturated. Equation 30 shows that core *b* remains saturated for a short interval after the beginning of the positive half-cycle of the supply voltage. The "cutoff angle" θ for core *b* is found from equation 30 as follows

$$\theta=\sin^{-1}\frac{E_c}{NE_s} \qquad (31)$$

The cutoff angle for core *a* one half-cycle later is found to be the same. The cutoff angles are shown in Fig. 4.

The firing angle for mode I can be found by taking the integral of equation 28 between adjacent cutoff angles

$$\int_\theta^{\pi+\theta}(e_a-e_b)d\omega t=0 \qquad (32)$$

As shown in Fig. 4 in the interval $\theta\le\omega t\le\alpha$, the circuit is in state 1. In the interval $\alpha\le\omega t\le\pi+\theta$ the circuit is in state 2. In the interval $\theta\le\omega t\le\alpha$, therefore, the voltage difference is

$$e_a-e_b=\frac{E_c}{N}$$

In the interval $\alpha\le\omega t\le\pi+\theta$, the voltage difference is

$$e_a-e_b=-e_s\left(1-\frac{R_L}{R_L'}\right)+\frac{E_c}{N}\frac{R_L}{R_L'}$$

The equivalent statement of equation 32 becomes

$$\int_\theta^\alpha\frac{E_c}{N}\,d\omega t-\int_\alpha^{\pi+\theta}\left[e_s\left(1-\frac{R_L}{R_L'}\right)-\frac{E_c}{N}\frac{R_L}{R_L'}\right]d\omega t=0 \qquad (32A)$$

The reactor voltages and the integrals in equation 32(A) are shown in Fig. 5 for a typical set of parameters.

In the interest of simplifying notation, two normalized parameters are introduced.

$$E\equiv\frac{E_c}{NE_s} \qquad (33)$$

$$R\equiv\frac{N^2R_L}{R_c} \qquad (34)$$

The integrations indicated in equation 32(A) are then performed, with the result

$$\cos\alpha=E[R\pi-\theta]-\cos\theta+E\alpha \qquad (35)$$

The cutoff angle θ has been shown in equation 31 to be a function of *E*. Equation 35 therefore gives the firing angle α as a function of *E* with *R* as a parameter. The solutions for α in this and in the three other modes are shown in Fig. 6.

The reactor voltage e_a and load current are plotted in Figs. 7 and 8 for two values of the resistance parameter *R*. The voltage e_a is similar to e_b, as shown in Fig. 5. For each value of the resistance parameter *R*, two firing angles are shown to illustrate the changes in the voltages and currents as the normalized input voltage is changed. The firing angle α is found from equation 35. The flux in core *b* is also shown in Fig. 8.

Since in mode I there is always at least one core unsaturated, the instantaneous values of control current and load current are always related through the turns ratio *N*. Thus, the rectified-average value of the load current is also related to the average control current by the turns ratio *N*.

$$I_L=NI_c \qquad (36)$$

The load current, from equation 29, can be formally averaged to obtain its rectified average value

$$I_L=\frac{1}{\pi}\int_\alpha^{\pi+\theta}\left(e_s+\frac{E_c}{N}\right)\frac{1}{R_L'}\,d\omega t \qquad (37)$$

This equation is integrated between the limits shown. If the resulting expression

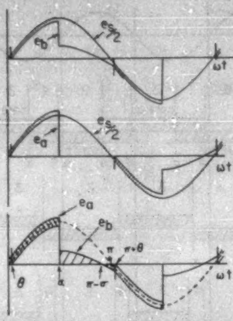

Fig. 5. Reactor voltages and integral of $e_a - e_b$ for amplifier with R = 3.33

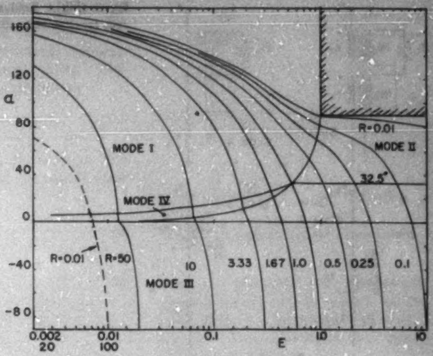
Fig. 6. Firing angle as function of E for series amplifier with d-c control



is manipulated and equation 35 is introduced at the strategic moment, the result is simply

$$I_L = \frac{E_c}{R_c} N \tag{38}$$

From this equation, or from the average flux theorem, it can be argued that the average control current is

$$I_c = \frac{E_c}{R_c} \tag{39}$$

The voltage gain of the amplifier is therefore

$$G_v = N \frac{R_L}{R_c} \tag{40}$$

The results given by equations 36 through 40 are identical with those given by Storm for comparatively low control resistance.[1] This is expected since the same approximation to the magnetization curve is used.

It next becomes necessary to define the range of the parameters E and R for which mode I exists. In describing mode I, two important assumptions were made. The first was that at the cutoff angle θ in each half-cycle, the load current goes to zero sinusoidally. At $\omega t = \theta$ the load current becomes zero because the total generated voltage in the load circuit is zero. This was expressed in equation 30, which can be rewritten

$$\frac{E_c}{Ne_s} = 1 \tag{30A}$$

It follows from this that if E_c/N is larger than the peak value of supply voltage E_s

$$\frac{E_c}{NE_s} = E > 1 \tag{41}$$

and equation 30 cannot be satisfied regardless of the value of the resistance parameter R. In this situation, the transformed control voltage appearing in the load circuit is so large that the supply voltage can never be large enough to make the total load circuit voltage zero. Thus, the circuit cannot enter state 1 from either state 2 or 3, and it has been shown that mode I cannot exist for values of the control voltage so that $E > 1$.

A second important assumption was implied in writing the equations for mode I. The existence of state 1 in the sequence of saturation states implies that $\alpha > \theta$. If, however, the cutoff angle were to increase while the firing angle decreased until the two angles were equal, then state 1 would disappear from the sequence and the circuit would enter a second mode of operation. Equation 35 shows that an increase in cutoff angle and a decrease in firing angle accompany an increase of E, and that they will become equal at values of E depending upon the resistance parameter R. Thus a lower boundary on the firing angle for mode I can be found by setting α equal to the cutoff angle θ in equation 35.

$$2 \cos \alpha = ER\pi \tag{42}$$

It has already been shown that mode I cannot exist for values of $E > 1$. Solutions of equation 42 are therefore desired for values of $E \leq 1$, for which $E = \sin \theta = \sin \alpha$. Equation 42 then becomes

$$\tan \alpha = \frac{2}{R\pi} \tag{43}$$

It is seen immediately that the right side of equation 43 is always positive. The firing angle on this boundary curve is always found between zero and 90 degrees. The boundary, shown in Fig. 6, is simply a plot of

$$\alpha = \sin^{-1} E \tag{44}$$

It should be noted that this is a boundary below which mode I cannot exist. It has not been shown, however, to be the greatest lower boundary on mode I. An attempt to prove this formally, in fact, has led to another mode called mode IV, to be discussed later.

The boundary of mode I, just determined, is defined by a change in the sequence of saturation states within the cycle. A second mode is suggested which is similar to mode I except that θ is everywhere equal to α.

Mode II

Mode II is characterized by an alternation of states 2 and 3. One of the two cores is always in the unsaturated state. This implies that a linear relation exists between the rectified-average value of the load current and the average value of the control current. Mode II is therefore a linear control region. It is shown schematically in Fig. 4(B).

If mode II is to exist over a finite range of the parameters, it is necessary merely to write the fundamental equation for the steady state and to define the region for which it is valid. The voltage-difference integral is taken over the interval of state 2. The voltage e_a is zero in this interval. From equation 15 the integral is written

$$\int_{\alpha}^{\pi+\alpha} e_b d\omega t = \int_{\alpha}^{\pi+\alpha} \left[e_s\left(1 - \frac{R_L}{R_L'}\right) - \frac{E_c}{N} \frac{R_L}{R_L'} \right] d\omega t = 0 \tag{28-II}$$

The solution is

$$\cos \alpha = ER \frac{\pi}{2} \tag{45}$$

This is identical with equation 43, showing

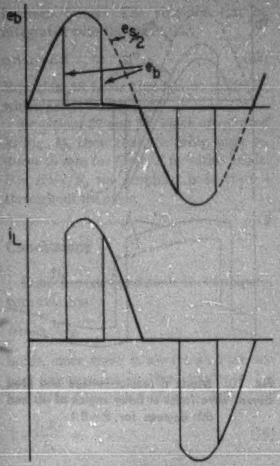


Fig. 7. Mode I reactor-voltage and load-current wave forms at firing angles of 60 and 120 degrees for R=50

that mode II includes the lower boundary defined for mode I.

In Fig. 6, equation 45 is used to plot the curves of firing angle as a function of E for mode II with R as the parameter. Figs. 9 and 10 show voltage and current wave forms for this mode for two values of the parameter R. On each diagram, firing angles of 40 to 60 degrees are shown.

In writing this integral equation it is tacitly assumed that at the angle α, the voltage e_b is positive. Reference to the polarities on the circuit of Fig. 1 shows that this is necessary if core b is to become unsaturated at the angle α when core a saturates. The limit for mode II will occur when e_b at the firing angle is exactly zero. This condition may be found by setting equation 15 equal to zero and evaluating at $\omega t=\alpha$. The result is

$$\sin\alpha=ER \tag{46}$$

Equation 46 may be divided by equation 45, yielding

$$\tan\alpha=\frac{2}{\pi} \tag{47}$$

$$\alpha=32.5^\circ \tag{48}$$

The interpretation of this equation is especially important since it suggests the form that mode III will take. On the boundary it was shown that the firing angle was given by equation 46. This can be rearranged slightly to read

$$\frac{E_s\sin\alpha}{R_L}=\frac{E_c}{R_c}N \tag{49}$$

Equation 49 shows that on the lower boundary of mode II, the limiting condition has been reached where at the firing angle of core a the load current produced by the supply voltage connected directly to the load is just enough to reduce the magnetomotive force on core b to zero. It has been shown that this boundary condition is reached at a firing angle of 32.5 degrees regardless of the circuit parameters.

This argument is easily extended to larger values of control voltage and smaller firing angles. There will be an interval after core a fires in which the load current and the control current flow independently. In this interval the supply voltage is small enough and the control voltage large enough so that the net magnetomotive force on core b at the firing angle α is not reduced to zero. The period in which the load and control currents flow independently will terminate when the supply voltage has become large enough to reduce the magnetomotive force on core b to zero. This situation is found only below the boundary defined by equation 46, however, and introduces a finite period of state 4 into the sequence. This new sequence defines a new mode, which is mode III.

Mode III

In mode III, there is an interval after the firing of core a in which both cores are saturated. This sequence is shown in Fig. 4(C). A positive voltage will appear on core b when the load current has attained the necessary value to make the magnetomotive force on the core equal to zero. The angle σ at which this occurs is defined by equation 46.

$$\sin\sigma=ER \tag{50}$$

The angle σ is plotted as a function of E with R as the parameter in Fig. 11. On the lower boundary of mode II, $\alpha=32.5$ degrees, it was shown that $\alpha=\sigma$. As expected, therefore, the curves of σ from Fig. 11 and the curves of α from Fig. 6 for $R\leq 1$ intersect on the boundary curve $\alpha=32.5$ degrees. For $R=1$, the curve of σ coincides with the boundary curve $\sin\alpha=E$, defined in equation 44.

Equation 28 is again applied to find α as a function of E. In mode II, the integral was taken between α and $\pi+\alpha$. In mode III the reactor voltage is zero between α and σ, so the integral is written

$$\int_\sigma^{\pi+\alpha}e_b\,d\omega t=\int_\sigma^{\pi+\alpha}\left[e_s\left(1-\frac{R_L}{R_L'}\right)-\frac{E_c}{N}\frac{R_L}{R_L'}\right]d\omega t=0 \tag{28-III}$$

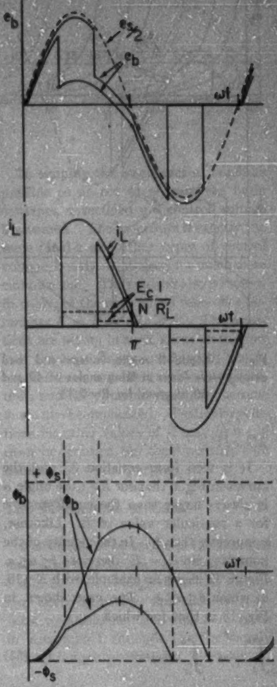

Fig. 8. Mode I reactor-voltage, flux, and load-current wave forms at firing angles of 60 and 120 degrees for R=3.33

The solution may be seen in the following equation

$$\cos\alpha-\alpha\sin\sigma=(\pi-\sigma)\sin\sigma-\cos\sigma \tag{51}$$

This equation is solved for the firing angle α, which is plotted as a function of E, with R as a parameter, in Fig. 6. It is seen from these figures that the firing angle in mode III extends to negative values. Typical voltage and current wave forms for mode III are shown in Fig. 12.

Between the firing angle defined in equation 51 and the angle σ defined by equation 50, it has been shown that an interval of state 4 exists in which both cores are saturated. It follows that mode III is not a linear control region. The general relation may be stated without further proof that for the load current to be a linear function of the control current, the circuit must be in a mode in which there is always at least one core unsaturated.

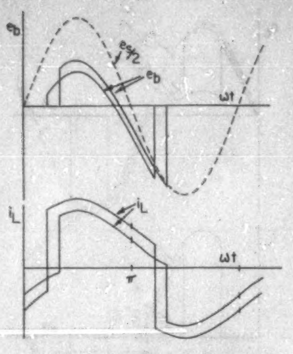

Fig. 9. Mode II reactor-voltage and load current wave forms at firing angles of 40 and 60 degrees for R=0.33

Mode IV

It is seen from equation 35 and the curves in Fig. 6 that for $R\geq 1$, the angle α is always larger than the cutoff angle θ for a particular value of E. Likewise, σ is greater than θ. In the vicinity of the boundary $\sin\alpha = E$, therefore $\theta\leq\alpha\leq\sigma$. Figure 13 shows an example, with $R=10$, in which $\theta\leq\alpha\leq\sigma$. The case shown in Fig. 13 is that for which

$$\int_{\theta}^{\alpha} e_b d\omega t+\int_{\alpha}^{\sigma} e_b d\omega t=0 \tag{52}$$

Core b is caused to return to the saturation point at the angle σ. In this example, the voltage e_b goes positive again at σ, and the flux change in the core reverses direction just in time to prevent core b from saturating again.

For smaller firing angles, core b reaches saturation again at the angle δ defined by the integral equation

$$\int_{\theta}^{\alpha} e_b d\omega t+\int_{\alpha}^{\delta} e_b d\omega t=0 \tag{53}$$

In the interval $\delta\leq\omega t\leq\sigma$ the circuit is in state 4. The sequence shown in Fig. 4(A) has been changed to that shown in Fig. 4(D).

The firing angle at which the transition from mode I to mode IV occurs can be determined by writing equation 52 in detail, using equation 8 and equation 15. When the integrations are performed, the result is found to be

$$\left(1-\frac{2R_L}{R_L'}\right)\cos\alpha+\left[2\left(1-\frac{R_L}{R_L'}\right)\sin\sigma-E\right]\alpha$$
$$=2\left(1-\frac{R_L}{R_L'}\right)(\cos\sigma+\sigma\sin\sigma)-E\theta-\cos\theta \tag{54}$$

This is a difficult equation to solve for α. Solutions were obtained directly by performing the graphical integrations indicated in Fig. 13 for various values of E. The resulting series of points defines the boundary between mode I and mode IV shown in Fig. 6.

In mode IV, the integral of the voltage difference e_a-e_b must still be zero in the steady state. The integrals are set up in a manner similar to those for the other three modes.

$$\int_{\theta}^{\alpha}\left(\frac{e_s}{2}+\frac{E_c}{2N}\right)d\omega t$$
$$=\int_{\sigma}^{\pi+\theta}\left[e_s\left(1-\frac{R_L}{R_L'}-\frac{E_c}{N}\frac{R_L}{R_L'}\right]d\omega t\right. \tag{28-IV}$$

The solution is

$$(\cos\theta-\cos\alpha)-E(\alpha-\theta)=2R[(\cos\sigma+\cos\theta)-\sin\sigma(\pi+\theta-\sigma)] \tag{55}$$

Solutions of equation 55 give the firing angle for mode IV as a function of E with R as a parameter, and are plotted in Fig. 6.

This reasoning holds for mode IV until the firing angle α reduces to the cutoff angle θ. In this case, the left side of equation 28-IV is zero, and the equation reduces to

$$\int_{\sigma}^{\pi+\alpha}\left[e_s\left(1-\frac{R_L}{R_L'}\right)-\frac{E_c}{N}\frac{R_L}{R_L'}\right]d\omega t=0 \tag{28-III}$$

Equation 54 is seen to be the defining equation, for mode III. This shows therefore that mode III and mode IV coincide on the boundary $\sin\alpha=E$.

In this discussion, four modes have been described. It has been shown that every part of Fig. 6 is included in one of the four modes except for the excluded region

$90°<\alpha<180°$
$E>1$

It was shown that if the circuit is in any one of the four modes, it cannot be brought into the excluded region through changes in the normalized voltage E or the normalized resistance R. It is therefore concluded that, subject to the assumed magnetic properties, all possible sequences of saturation states have been accounted for.

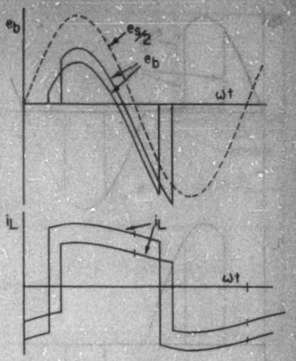

Fig. 10. Mode II reactor-voltage and load current wave forms at firing angles of 40 and 60 degrees for R=0.1

Series Amplifier with Rectified A-C Control

One of the factors which adds to the complication of the analysis of the series amplifier with d-c control is the fact that the direct voltage is at times larger than the a-c supply voltage. This causes the reactor voltage in states 2 and 3, equations 15 and 20, to go through zero at the angles σ and $\pi-\sigma$. That the control voltage is finite when the supply voltage goes through zero also accounts for the fact that the cutoff angle differs from zero. A considerable simplification in the analysis results if the control voltage is assumed to be a full-wave-rectified sine wave of the same frequency and phase as the supply voltage. The amplitude of the voltage is the variable. If the circuit is assumed to be in mode I, the voltage-difference integral can be written for the interval $0\leq\omega t\leq\pi$.

$$\int_{0}^{\alpha}\frac{E_c}{N}\sin\omega t\, d\omega t-$$
$$\int_{\alpha}^{\pi}\left[E_s\left(1-\frac{R_L}{R_L'}\right)-\frac{E_c}{N}\frac{R_L}{R_L'}\right]\times$$
$$\sin\omega t\, d\omega t=0 \tag{56}$$

The firing angle can be found by integrating equation 56.

$$\cos\alpha=\frac{E(1+2R)-1}{E+1} \tag{57}$$

It should be noted with care that when the symbol $E=E_c/NE_s$ is used, the quantity E_s is the peak value of the rectified sine wave used for control, not the average value.

Equation 57 is valid so long as the conditions for mode I are not violated. For $E>1$, the voltage applied to reactor b during the interval $0\leq\omega t\leq\alpha$ is negative. State 1 therefore drops out of the sequence, and the amplifier is in mode II. The first integrand of equation 56 becomes the same as the second, but with a plus sign between terms. The equation can be integrated with the result that

$$\cos\alpha = ER \qquad (58)$$

Equation 58 holds throughout mode II, which exists for all $E \geq 1$.

Equations 57 and 58, which are plotted in Fig. 14, show that the firing angle reduces to zero for $E = 1/R$ for either mode. For $E > 1/R$, the amplifier is in state 4 throughout the cycle.

Conclusions

In both mode I and mode II the ampere-turn relation

$$N_cI_c = N_gI_L$$

holds, since there is always at least one core unsaturated in these modes. If a normalized output voltage is defined as

$$V = \frac{I_LR_L}{E_s} \qquad (59)$$

the normalized gain can be written

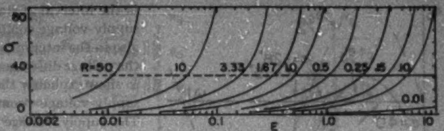
$$\frac{V}{E} = R \qquad (60)$$

where the normalized input voltage and the resistance parameter are defined by equation 33 and equation 34 respectively. Applied to the case of rectified a-c control, the control voltage E_c is replaced by the average value of the rectified a-c control voltage. Equation 60 becomes

$$\frac{V}{2E/\pi} = R \qquad (60A)$$

The results of this analysis may be of some use in applications where the series amplifier is still used. The important results of the analysis, however, is the method of approach. Two elementary and well-known theorems have been used to obtain equation 28. This equation has then been used to define the modes of operation and to find the firing angle as a function of control voltage. The roles of control-circuit impedance and control voltage in determining the mode of operation have been shown. For other assumed control voltages, magnetic characteristics, and perhaps such things as time-varying impedances, the integration indicated in equation 28 can be performed over the piecewise linear ranges corresponding to the saturation states in the modes. This has been done for hysteresis loops having slope and width, which complicates the analysis somewhat. The important point to be made, however, is that although it may be difficult to obtain particular solutions, the approach to the problem is unchanged. Often one can predict the effects of such disturbing phenomena without carrying out the detailed solutions.

Fig. 11. Curves of σ as function of E with R as parameter



No attempt has been made here to discuss all of the observed properties of the series amplifier. These are well known, and are covered thoroughly in the classic works of Storm.[1-3] In Part II it will be shown that equation 28 also gives a simple and clear picture of the mechanisms of gain and time constant of the series amplifier.

Part II—The Mechanisms of Gain and Time Constant

In Part I, the control-circuit voltage and resistance were included in the equations for the series amplifier. This was a crucial step, since it was only by this that it was possible to make effective use of the average-flux theorem and the symmetry theorem, from which was deduced the important steady-state equation

$$\int_{\omega t}^{\omega t+\pi}(e_b - e_a)d\lambda = 0 \qquad (28)$$

Careful examination of this equation in Part I showed that it could be used to define the four characteristic steady-state modes of operation of the amplifier with d-c control, and the two characteristic modes of operation of the amplifier with rectified a-c control. It showed also that altering the control voltage and the assumptions regarding the magnetization curve would alter the details of the solution, but not the method of approach so long as the control voltage is periodic at twice the power supply frequency.

Part II goes little further than to interpret equation 28. It is shown that this equation contains all the information necessary to give a clear picture of the mechanism of gain, and the mechanism of time constant, or delay, and their relation to one another. It is shown how the control voltage physically controls the amplifier and that the gain and time constant are consequences of the same basic mechanism of control. The results as applied to the series amplifier are incidental. It is hoped that the concepts developed will find application in the analysis of magnetic amplifiers in general.

To simplify the mechanics as much as possible so as not to obscure the basic concepts, a rectified a-c control voltage is assumed. The procedure is exactly the same for d-c and other types of control voltage, but the details become much more cumbersome. The analysis also is limited to values of the normalized resistance parameter $R = R_LN^2/R_c \gg 1$. The equations are set up in such a way as to show how the argument proceeds when this is not the case, but the graphic interpretations and the dynamic equations become much more complicated. Particular solutions for other values of R may in many cases be required, but their inclusion here does not serve the purpose.

The Mechanism of Gain

The circuit to be used and the assumed magnetic characteristics are shown in Figs. 1 and 2. The voltage equations for the two electrical meshes and the two magnetic equations for the cores were given in equations 1 through 4. The supply voltage is again given by

$$e_s = E_s \sin\omega t$$

The d-c control voltage in the equations must be replaced by

$$e_c = E_c \sin\beta \qquad (61)$$

where the argument β is measured in radians from the beginning of the half-cycle in question and ranges over the values $0 \leq \beta \leq \pi$. The control voltage is a rectified sine wave of the same frequency and phase as the supply frequency. The amplitude is the variable. The positive polarity of the control voltage is taken the same as the positive d-c control voltage.

In Part I the solutions for reactor voltages and currents in state 1 were given in equations 6 through 8. In state 2 the solutions were given by equations 13 through 15. In state 3 the solutions were given by equations 18 through 20. In state 4, the solutions were given by equations 21 through 24. These equations may be found by reference to Part I or they can easily be derived by inspection of the circuit.

It is convenient to take the integral of equation 28 over the half-cycle $0 \leq \omega t \leq \pi$.

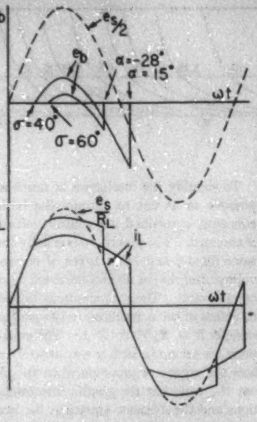


Fig. 12. Mode III reactor-voltage and load-current wave forms at firing angles of 15 and −28 degrees, σ of 40 and 60 degrees

$$\int_0^\pi (e_b-e_a)d\omega t=0 \qquad (62)$$

In the interval $0\leq\omega t\leq\alpha$ the circuit is in state 1. Neither core is saturated and the voltage difference is determined from equations 7 and 8.

$$e_b-e_a=-e_c/N \quad (0\leq\omega t\leq\alpha) \qquad (63)$$

During the remainder of the half-cycle, core a is saturated and the voltage e_a is zero. The voltage difference is just e_b, and is given by equation 15.

$$e_b-e_a=e_s\left(1-\frac{R_L}{R_L'}\right)-\frac{e_c}{N}\frac{R_L}{R_L'}(\alpha\leq\omega t\leq\pi) \qquad (64)$$

Equation 62 then becomes, for the steady state

$$-\int_0^\alpha \frac{e_c}{N}d\omega t+\int_\alpha^\pi\left[e_s\left(1-\frac{R_L}{R_L'}\right)-\frac{e_c}{N}\frac{R_L}{R_L'}\right]d\omega t=0 \qquad (65)$$

The half-cycle chosen is one in which the supply voltage is positive. In the negative half-cycle, however, e_b-e_a is found to be the same, i.e., it is periodic at twice the supply frequency.

The voltage wave forms involved are shown in Fig. 15. The equivalent circuits for the two saturation states are also shown. The voltage wave form consists of a control-voltage component $-e_c/N$ in the interval of state 1, $0\leq\omega t\leq\alpha$, a control voltage component

$$-\frac{e_c}{N}\frac{R_L}{R_L'}$$

in the interval of state 2, $\alpha\leq\omega t\leq\pi$, and a supply-voltage component $e_s(1-R_L/R_L')$ also in the interval of state 2. In Fig. 16 the voltage difference in Fig. 15 is redrawn to show explicitly the control-voltage and supply-voltage components of e_a-e_b. The supply voltage and half the supply voltage are also included in Fig. 16. The particular example chosen for Figs. 15 and 16 is the one that was used for Fig. 17 with $R=3.33$. The firing angle is 120 degrees. This example is used because the voltage difference is of proportions which can easily be seen when drawn to the same scale as the supply voltage.

Virtually all of the generalizations regarding the control and response of the magnetic amplifier will be based on the diagram in Fig. 16 and the voltage-difference integral, equation 62.

The equivalent circuits in Fig. 15 show the physical source of the difference-voltage components. In state 1, the difference between the two reactor voltages is simply the control voltage reduced by the turns ratio N, since no current flows in the control winding. In state 2, core a is saturated and core b is unsaturated. Core b acts as a perfect transformer during this period. The control-voltage and supply-voltage components of e_b can be found separately by considering one voltage generator at a time. Equation 64 was obtained in this manner. If equation 64 is rewritten in terms of the parameter R, the voltage difference is separated into supply-voltage and control-voltage components as follows

$$e_b-e_a=e_s\left(\frac{1}{1+R}\right)-\frac{e_c}{N}\frac{R}{1+R}\quad \alpha\leq\omega t\leq\pi \qquad (66)$$

It will be shown that when the supply-voltage component is small and the control-voltage component large, the gain of the amplifier is large. From equation 66 this is found to be the case for large values of R. In Part I, in fact, R was found in equation 60 to be equal to the normalized voltage gain of the amplifier. The only limit to the gain of the amplifier is the existence of the supply-voltage component in equation 66. This exists because of the fact that load current is always required to flow through an unsaturated core in mode I.

The wave forms in Fig. 16 represent the steady state for a particular value of the control voltage e_c/N. The integrals of the components that make up e_b-e_a must sum to zero. If the control voltage is increased by an amount $\Delta e_c/N$, the control voltage components in Fig. 16 increase in the negative direction by the amount $\Delta e_c/N$ from 0 to α, and

$$\frac{\Delta e_c}{N}\frac{R_L}{R_L'}$$

from α to π. The positive component of the voltage difference is derived from the load current and is a section of the sine wave, $e_s(1-R_L/R_L')$, whose magnitude is independent of the control voltage. The additional positive voltage integral required to balance the added negative integral is therefore obtained by a decrease in the firing angle α. Associated with this change of firing angle is a corresponding change in the average output voltage E_0. In Fig. 16, an increment of control voltage is shown producing an increase in the negative component of the integral of e_b-e_a. The area shaded under the positive voltage component $e_s(1-R_L/R_L')$ is therefore equal to the negative integral component. The change in firing angle shown is that required to produce this equality. The large unshaded area under the voltage e_s is very nearly the increase of the output voltage integral.

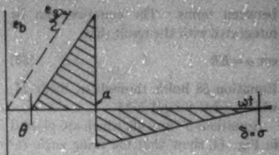

Fig. 13. Enlarged view of reactor voltage e_b on the boundary between mode I and mode IV for R=10

Before the increment of control voltage is applied, the control voltage components of e_b-e_a produce a negative voltage integral, as shown in Fig. 16. This quantity will be identified by the following symbol

$$\int e-=\frac{E_c}{N}(1-\cos\alpha)+\frac{E_c}{N}\frac{R_L}{R_L'}(1+\cos\alpha)$$

In the remainder of the argument it will be assumed that $R>>1$. Then

$$\int e-=\int_0^\pi\frac{e_c}{N}d\omega t=2\frac{E_c}{N} \qquad (67)$$

$$\int e+=\int_\alpha^\pi e_s\left(1-\frac{R_L}{R_L'}\right)d\omega t$$

The supply-voltage component of e_b-e_a is identified by

$$\int e+=\int_\alpha^\pi e_s\left(\frac{1}{1+R}\right)d\omega t \qquad (68)$$

When an increment of control voltage is applied, the firing angle begins to de-

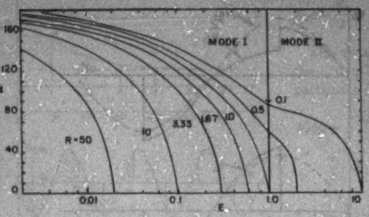

Fig. 14 (left). Firing angle as function of E for series amplifier controlled with full-wave-rectified sine wave of voltage

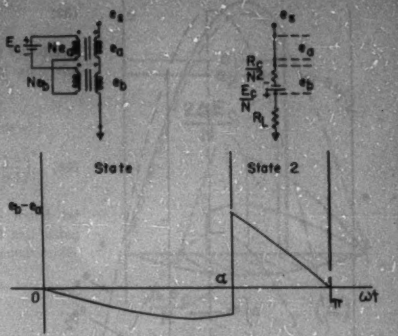

Fig. 15 (right). Diagram of voltage difference e_b-e_a for one half-cycle

crease, and continues to do so until the new steady-state condition shown in Fig. 16, is reached. When the new steady-state condition has been reached, the firing angle $\alpha'=\alpha+\Delta\alpha$ will be reduced sufficiently so that

$$\Delta\int e_- = \Delta\int e_+$$

Thus

$$\frac{2\Delta E_c}{N} = \int_{\alpha'}^{\alpha} e_s\left(\frac{1}{1+R}\right) d\omega t \qquad (69)$$

This voltage integral can on the right of equation 69 be treated as the increment of control-voltage integral. For larger values of R, the amplitude of the sine wave

$$e_s\left(\frac{1}{1+R}\right)$$

is smaller. Therefore, to satisfy equation 69 the change of firing angle will be increased. But the output is governed directly by this firing angle as shown in Fig. 16. The change in output voltage integral is approximately given by

$$\Delta E_o\pi = \int_{\alpha'}^{\alpha}\left[e_s - e_s\left(\frac{1}{1+R}\right)\right] d\omega t \approx \int_{\alpha'}^{\alpha} e_s\left(\frac{R}{1+R}\right) d\omega t \qquad (70)$$

The ratio of this to the equivalent input voltage integral from equation 69 is equal to the ratio of the increment in average output voltage to the increment in average input voltage.

$$\frac{\Delta E_o}{\Delta 2E_c/N\pi} = R \qquad (71)$$

This expression for the voltage gain is seen to be equivalent to the result obtained in equation 60.

There are two important points to be made regarding the expression for normalized voltage gain of the amplifier. The first is that by means of the ampere-turn equality the voltage gain in equation 60 was written with no restrictions on the value of R. The second point is that from the wave form of the voltage difference in Fig. 16, the voltage gain has been read directly. This step is of considerable significance because a simple diagram has been found which shows the mechanism by which a change in control voltage produces a change in output voltage. By extending these concepts a bit further, it is not difficult to see that the time constant is explained in terms of this same mechanism.

The Mechanism of Time Constant

The diagram in Fig. 16 and the arguments that were used to develop the mechanism of gain also imply the mechanism of time constant. Before enlarging on this point, however, the notion of "flux charge" will be developed.

In Fig. 17 flux wave forms were shown corresponding to the reactor voltages in the steady state. It was noted that for core b at $\omega t=0$, the flux starts from saturation and increases to a maximum value at $\omega t=\pi$. This maximum flux increment is called the flux charge. It corresponds to an integral of voltage over a finite angular interval, and therefore it has no meaning as a continuous function of the angular variable ωt. For physical reasons soon to be apparent the value is defined of the function flux charge at the end of the half-cycle in which it is accumulated. It is a discrete function of the index n, which will be used to number the half-cycles of the supply voltage. Note that the flux charge gained by core b on the first half-cycle is discharged on the second half-cycle. At the end of the nth half-cycle the flux discharged in the core during the half-cycle will be represented and called "flux charge," recognizing that the voltage integral that produced it occurred on the previous half-cycle. Further, voltage integrals will be called "fluxes" although this is not quite correct dimensionally.

To rid the equations of the constant ω, the normalized flux will be used

$$\phi = BA\omega$$

where B is flux density and A is the cross-sectional area of the magnetic path.

The discrete function flux charge therefore has a value at the end of each half-cycle equal to the flux discharged by the firing core in that half-cycle. Its value is measured alternately in cores a and b. It can easily be shown that the flux discharged by the firing core in a given half-cycle and the output voltage integral during that half-cycle add up to a constant. The flux discharged by core a, for instance, in a particular half-cycle is

$$N_g\phi_a = \frac{1}{2}\int_0^{\alpha}\left(e_s+\frac{e_c}{N}\right) d\omega t$$

The integral of half the output voltage in that half-cycle is

$$\frac{1}{2}E_o\pi = \frac{1}{2}\int_{\alpha}^{\pi}\left(e_s+\frac{e_c}{N}\right) d\omega t$$

It is seen that the sum of the two equals one-half the integral of the supply voltage plus the control voltage. Fig. 18 shows the relation of these to the index n.

In the steady state, equation 62 implies that the flux discharged by one core is equal to the flux charge gained in the other during any given half-cycle. If a half-cycle is considered in which core a fires, the flux discharged by core a is already determined. The integral of the voltage difference gives the increment of flux charge during the half-cycle, and appears directly as an increment in the flux charge gained by core b during that half-cycle. Thus, in the steady state

$$\delta N_g\phi = \int_0^{\pi}(e_b-e_a) d\omega t = 0 \qquad (62A)$$

The right side of this equation is expanded in equation 65.

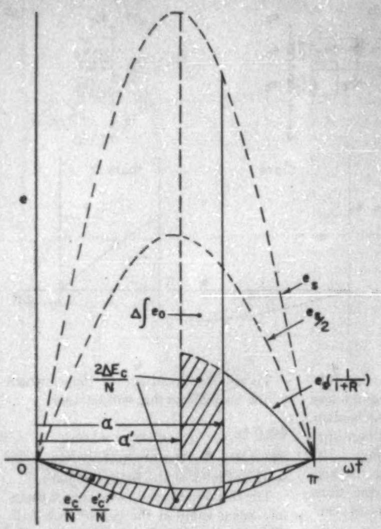

Fig. 16 (left). Diagram of voltage difference $e_b - e_a$ in Fig. 15 redrawn to show negative and positive components

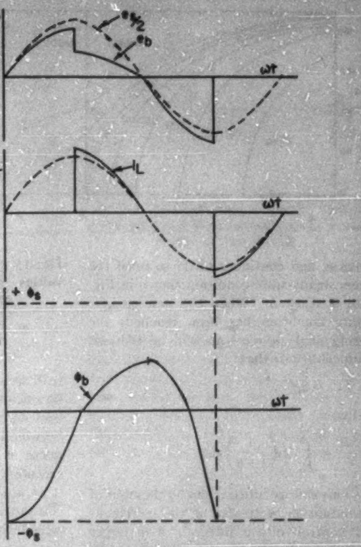

Fig. 17 (right). Reactor voltage, load-current, and flux wave forms for rectified sine wave control, R=3.33

An increment of control voltage is now applied. If it is assumed that $R>>1$ and that during the first half-cycle the firing angle does not change, equation 65 yields the following

$$\delta N_g\phi_1 = \int_0^\pi (e_b - e_a)d\omega t \approx \int_0^\pi \frac{\Delta e_c}{N}\, d\omega t = -\frac{2E_c}{N} \quad (72)$$

This is the amount by which the flux discharged by core *b* decreases in the second half-cycle. A diagram showing these relations is shown in Fig. 19(A). In this diagram, the voltage that discharges core *b* on the second half-cycle is shown superimposed on the voltage that discharges core *a* on the first half-cycle. The firing angle is shown decreased to account for the decrease in the flux charge gained by core *b* on the first half-cycle, given by equation 72. It is not strictly true that the firing angle does not change on the first half-cycle, because the voltage discharging core *a* has increased by a small amount. This correction factor will be included later in the argument. At present, the important point to be made is that the integral of the voltage difference gives the change in flux charge on any half-cycle, and that this increment can be readily identified on a diagram of the voltage difference such as Fig. 16.

Consider now the events that occur in the general or *n*th half-cycle. The firing angle is α_n. The new control voltage is $e_c' = e_c + \Delta e_c$. The increment of flux charge on the *n*th half-cycle is then

$$\delta N_g\phi_n = N_g(\phi_{n+1} - \phi_n) = \int_{(n-1)\pi}^{n\pi} (e_b - e_a)d\omega t \quad (73)$$

This can be expanded as follows

$$\delta N_g\phi_n = -\int_0^{\alpha_n} \frac{e_c'}{N}\, d\omega t + \int_{\alpha_n}^{\pi} \left[e_s\left(\frac{1}{1+R}\right) - \frac{e_c'}{N}\frac{R_L}{R_L'} \right] d\omega t \quad (74)$$

If it is assumed that $R>>1$, equation 74 can be rewritten

$$\delta N_g\phi_n = -\int_0^\pi \frac{e_c'}{N} d\omega t + \int_{\alpha_n}^{\pi} e_s\left(\frac{1}{1+R}\right) d\omega t \quad (75)$$

The integration in equation 75 is then performed.

$$\delta N_g\phi_n = -\int_0^\pi \frac{e_c}{N} d\omega t + \int_{\alpha}^{\pi} e_s\left(\frac{1}{1+R}\right) d\omega t - \int_0^\pi \frac{\Delta e_c}{N}\, d\omega t + \int_{\alpha_n}^{\alpha} e_s\left(\frac{1}{1+R}\right) d\omega t \quad (76)$$

The first half of equation 76 is zero from equation 65. Equation 76 then becomes

$$\delta N_g\phi_n = -\frac{2\Delta E_c}{N} + E_s\left(\frac{1}{1+R}\right)(\cos\alpha_n - \cos\alpha) \quad (77)$$

The term cos α was given by equation 57

$$\cos\alpha = \frac{E(1+2R)-1}{E+1} \quad (57)$$

This is a function only of the normalized resistance and voltage parameters, and is not a function of the index *n*. It therefore can be treated as a constant.

The term cos α_n can be found by integrating the following in terms of the flux discharged on the *n*th half-cycle

$$N_g\phi_n = \int_0^{\alpha_n} \left(\frac{E_s}{2} + \frac{E_c'}{2N}\right) \sin\omega t\, d\omega t \quad (78)$$

$$N_g\phi_n = \frac{E_s}{2}(1+E')(1-\cos\alpha_n)$$

for $R>>1$, it is shown from equation 58 that $E'<<1$.

$$\cos\alpha_n = 1 - \frac{2N_g\phi_n}{E_s} \quad (79)$$

Equation 77 can then be rewritten

$$N_g\phi_{n+1} - N_g\phi_n = -\frac{2\Delta E_c}{N} + E_s\left(\frac{1}{1+R}\right)\left(1 - \frac{2N_g\phi_n}{E_s} - \cos\alpha\right) \quad (80)$$

$$N_g\phi_{n+1} - \left(1 - \frac{2}{1+R}\right)N_g\phi_n = -\frac{2\Delta E_c}{N} + E_s\left(\frac{1}{1+R}\right)(1-\cos\alpha) \quad (81)$$

Equation 81 is a first-order difference equation. The right side of the equation is a constant driving function. The complementary solution is exponential, and since the driving function is a step function multiplied by a constant, the total re-

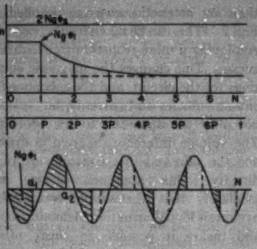

Fig. 18. The discrete function "flux charge" as function of index n. Index n placed at end of half-cycle to which it refers

sponse, which is a discrete function of n, has an exponential envelope. The complementary equation is then

$$\left[D-\left(\frac{R-1}{R+1}\right)\right]N_g\phi_n=0 \tag{82}$$

The solution is assumed

$$N_g\phi(t)=C\epsilon^{-nP/T} \tag{83}$$

The constant T is the time constant. The constant P is the time of one half-cycle, as shown in Fig. 18. Equation 83 is the flux charge as a function of time. The variable in the exponent nP indicates that the function is to be evaluated only at these discrete values of time. It can be written as a function of the index n to conform with the notation in equation 81 by simply regrouping.

$$N_g\phi_n=C[\epsilon^{-P/T}]^n=C[\epsilon^m]^n \tag{84}$$

where $m=-P/T$. Equation 84 is recognized to be in the form usually selected for the complementary function of the first-order difference equation. The symbol C is an arbitrary constant; m is a parameter. By placing this form of $N_g\phi_n$ in equation 82, the solution can be found in the usual manner. The result is

$$\epsilon^m=\left(\frac{R-1}{R+1}\right) \tag{85}$$

After the new steady state is reached, equation 81 can be written since it is known that $N_g\phi_{n+1}=N_g\phi_n=N_g\phi'$

$$N_g\phi'\left(1-\frac{R-1}{R+1}\right)=-\frac{2\Delta E_c}{N}+E_s\left(\frac{1}{1+R}\right)(1-\cos\alpha) \tag{86}$$

$$N_g\phi'=-\frac{\Delta E_c(1+R)}{N}+\frac{E_s}{2}(1-\cos\alpha) \tag{87}$$

The initial condition is found in the same manner. Before the control voltage is increased it has the value e_c. Also, $N_g\phi_{n+1}=N_g\phi_n=N_g\phi$.

$$N_g\phi=\frac{E_s}{2}(1-\cos\alpha) \tag{88}$$

The total solution is found by adding the complementary solution and the particular integral

$$N_g\phi_n=-\frac{\Delta E_c(1+R)}{N}+\frac{E_s}{2}(1-\cos\alpha)+c\left(\frac{R-1}{R+1}\right)^n \tag{89}$$

The arbitrary constant is found by putting $n=0$ in equation 89 and using the initial value of $N_g\phi_n$ from equation 88.

$$C=\frac{\Delta E_c(1+R)}{N} \tag{90}$$

Equation 89 then becomes

$$N_g\phi_n=\frac{E_r}{2}(1-\cos\alpha)-\frac{\Delta E_c(1+R)}{N}\left[1-\left(\frac{R-1}{R+1}\right)^n\right] \tag{91}$$

If it is recognized that the assumption of $R>>1$, already made, results in a response which is slow compared to the time of a half-cycle P, the exponent in equation 84 is small compared to unity. In that event, the exponential can be fairly well represented by a few terms of its power series

$$\epsilon^{-P/T}=1+\left(-\frac{P}{T}\right)+\frac{(-P/T)^2}{2!}+\frac{(-P/T)^3}{3!}+\dots$$

If the first two terms only are taken, equation 84 can be equated to equation 85.

$$1+\left(-\frac{P}{T}\right)=\frac{R-1}{R+1}$$

$$\frac{P}{T}=2\left(\frac{1}{1+R}\right) \tag{92}$$

But $1+R\doteq R$ and $P=1/2f$. Thus the time constant becomes

$$T=\frac{1}{4f}R \tag{93}$$

This is seen to be the expression for time constant developed by Storm[8] for the series amplifier with comparatively low control resistance.

Fig. 19(B) shows the graphical representation of the change in flux charge in the nth half-cycle. These relations were written in terms of two adjacent half-cycles. The flux discharged in the first half-cycle, as shown in Fig. 18, is not affected by the increment of control voltage during that half-cycle. The exponential decay of flux charge, corresponding to an exponential rise in output voltage, therefore begins one half-cycle after the switch is closed, applying the increment of control voltage. The response of the amplifier can therefore be represented in terms of a d-c gain, one time constant, and a real displacement of one half-cycle. The real displacement of one half-cycle, however, is only approximate. The flux discharged does not change in the first half-cycle, but the firing angle, and therefore the output voltage, does change somewhat because the increment of control voltage discharges the firing core in a shorter period. If the quiescent firing angle is nearly 180 degrees, the change in firing angle will be as much as half that indicated for the first half-cycle in Fig. 19(A). The real displacement therefore may be as small as 1/4 cycle. Also, the displacement will depend upon the exact time at which the increment of control voltage is applied.

The voltage transfer function for the amplifier can therefore be written, assuming a half-cycle displacement

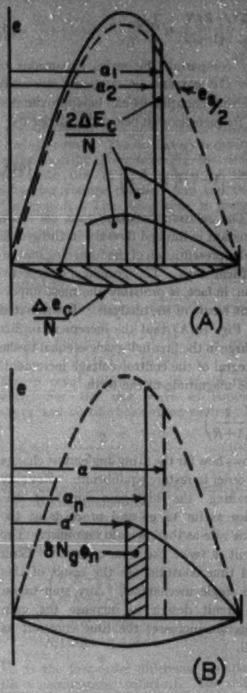

Fig. 19. Voltage diagrams which relate gain and time constant

$$\frac{E_o}{E_{in}}=\frac{R/N}{(1+Ts)}\epsilon^{-(\pi/\omega)s} \tag{94}$$

By comparing the series expansions of $\epsilon^{-(\pi/\omega)s}$ and $(1+\pi/\omega s)^{-1}$, one can easily see that equation 94 can be approximated at frequencies well below the carrier by

$$\frac{E_o}{E_{in}}=\frac{R/N}{(1+Ts)\left(1+\frac{\pi}{\omega}s\right)} \tag{94A}$$

The relation between gain and time constant is implied directly in the graphical representation of the foregoing mathematical steps. This graphical interpretation, in fact, is probably the most important result of the analysis. It was noted in Fig. 19(A) that the increment in flux charge in the first half-cycle is equal to the integral of the control-voltage increment. The magnitude of the term

$$e_s\left(\frac{1}{1+R}\right)$$

shows how far the firing angle must change in order to restore equilibrium. Roughly speaking, the high-gain amplifier has twice as far to go and proceeds at the same rate as the low-gain amplifier. The result is twice the time constant. Gain and time constant are the result of this one single mechanism. Any step taken in circuit design to increase the gain therefore increases the time constant as well.

Conclusions

All magnetic amplifiers that display the proper symmetry conditions and assume the magnetic properties of Fig. 2 yield diagrams of the voltage difference similar to that of Fig. 16. If the diagram for the parallel amplifier is drawn, it is easily seen that it has twice the gain and four times the time constant of the series amplifier. If external feedback is applied, the effect is merely to reduce the current flowing in the control winding by causing some of it to flow in the feedback windings. This reduces the voltage

$$e_s\left(\frac{1}{1+R}\right)$$

and increases the gain. Obviously, the time constant is also increased because the model which has been developed is unchanged.

In the case of the simple series and parallel amplifiers, the gain is relatively low and the control current is relatively large. The error in assuming the magnetic characteristic of Fig. 2 is small if the coercive force of the magnetic material is small and the hysteresis loop is nearly rectangular. When large amounts of positive feedback are used, or the current in the unsaturated reactor is blocked by means of rectifiers, the control current becomes of the same order of magnitude as the error assumed in making the assumptions on magnetic materials implied in Fig. 2. This can be taken into account by employing a more realistic magnetization curve. This changes the magnetic equations for the circuit, and the solutions for circuit voltages and currents, but it does not alter the approach to the problem. The voltage-difference diagram is drawn and the gain and time constant are read directly. This approach shows immediately that the simple rectangular hysteresis loop is an untenable assumption, and makes it possible to check other simple magnetic models fairly quickly. A subsequent paper will show the results of this procedure applied to the common "self-saturating" magnetic amplifiers.

◆

Discussion

H. C. Bourne, Jr. (University of California, Berkeley, Calif.): Part I of the paper is interesting as a good exercise in the steady-state solution of a piecewise linear circuit. As could be anticipated with these particular excitations, the transcendental equations encountered limit the usefulness of the results in any attempt to represent this magnetic amplifier as a systems component.

The discusser is frankly puzzled by the claims made and the results obtained in Part II of this paper. The author should certainly be aware of the paper by Johannessen.[1] Equation 28 is only a restricted form of the determining equation represented by equation 10 of the reference. With sinusoidal excitation and rectified a-c control the assumption $R>>1$ seems hardly necessary and, in fact, obscures important gain-bandwidth concepts. The mechanism of gain and time constant could not be expressed more clearly and in a more useful form than in equation 13 of Johannessen's paper, in which no assumption involving R is used. The dynamic transfer function of equation 15 of the reference with an appropriate change of symbols

$$G(s)=\frac{\frac{1}{N}\frac{R}{R+1}\left(1+\epsilon^{-\frac{\pi}{\omega}s}\right)}{1-\frac{R-1}{R+1}\epsilon^{-\frac{\pi}{\omega}s}}=\frac{K_1(z+1)}{z-K_2}$$

in which

$$z=\epsilon^{-\frac{\pi}{\omega}s}$$

is reduced to the author's result as a special case. The addition of a half-cycle delay to equation 94 hardly seems justified since the approximation involving the use of T for the time constant has already implied that this delay is negligible. There are other subtleties of this nature concerning the approximations involved in a simplification of $G(s)$, i.e.

$$\left(\epsilon^{-\frac{\pi}{\omega}s}\cong 1-\frac{\pi}{\omega}s \text{ and } \epsilon^{-\frac{\pi}{\omega}s}\cong 1+\frac{\pi}{\omega s}\right)$$

which call for some care in interpretation.

Neither the author nor Johannessen considers the case of dynamic operation in mode II. Dynamically, the behavior of the circuit is different in the two modes, as indicated by Ringelman and Fenaroli[2] and emphasized in the discussion of their paper. From gain-bandwidth considerations, the circuit as a systems component would seldom be designed to operate in this mode.

R. C. Barker: The transcendental equations of Part I are those required to give the firing angle as a function of the control voltage and the circuit parameters. The appearance of these equations does not alter the fact that the static gain of the amplifier, as shown in equation 38 and in the conclusion, is the same constant as it is for rectified a-c control. The procedure for finding the frequency response is the same as for rectified a-c control, and the results are substantially the same. But the algebra is somewhat more complicated.

The author is grateful to Mr. Bourne for reminding us of the excellent work done at Massachusetts Institute of Technology relevant to this subject. The results obtained by Johannessen are virtually the same as those given in the foregoing, although his paper was written with a somewhat different purpose. The "determining equation" of the reference is the same as the author's equation 25 in Part I. Equation 25 was here written for the steady state. In Part II, the quantity "flux charge" is discussed at length, and it is argued that equation 25 holds in the dynamic case as well, leading to the interpretation of the voltage-difference integral as a flux-charge increment in equation 62(A). This simple physical identification of the induced voltage at the control terminals with the reactor fluxes is the reason for the author's, dealing with reactor fluxes directly rather than with output voltages. One can relate the output-voltage integral to the reactor fluxes, as pointed out prior to Equation 62(A), by writing

$$E_{o_n\pi}=\frac{2R}{1+R}[E_s(1+E_n)-N_g\varphi_n] \qquad (95)$$

This can be written by inspection from Fig. 16 as well. In this manner, the increment in output-voltage integral is related to the increment in flux charge by

$$\delta E_{o_n\pi}=\frac{2R}{1+R}[E_s(E_{n+1}-E_n)-\delta N_g\varphi_n] \qquad (96)$$

The assumption of $R>>1$ is made entirely to simplify the algebra in the example chosen for this paper, and does not alter the resulting gain or bandwidth. The procedure for writing the difference equation exactly is the same as that followed in the paper. The author recommends, as an exercise, starting with equation 67 and working the problem with no assumptions regarding the value of R. The algebra multiplies rapidly, but the conclusions are only slightly different. The increment in output-voltage integral, equation 70, becomes

$$\Delta E_{o\pi}=\int_{\alpha^1}^{\alpha}\left(e_s+\frac{e_c'}{N}\right)\left(\frac{R}{1+R}\right)d\omega t+\int_{\alpha}^{\pi}\frac{\Delta e_c}{N}\left(\frac{R}{1+R}\right)d\omega t \qquad (70\text{A})$$

Integration of equation 74 exactly gives in place of equation 77

$$\delta N_g\varphi_n=\frac{\Delta E_c}{N}\left[\cos\alpha_n-\left(\frac{R}{1+R}\right)\cos\alpha-\left(\frac{1+2R}{1+R}\right)\right]+\left(\frac{E_c-\Delta E_cR}{N(1+R)}+\frac{E_s}{1+R}\right)[\cos\alpha_n-\cos\alpha] \qquad (77\text{A})$$

The resulting difference equation is

$$N_g\varphi_{n+1}-\left(\frac{R-1}{R+1}\right)N_g\varphi_n=-\frac{2\Delta E_c}{N}\left(\frac{R}{1+R}\right)+\frac{E_s+E_c/N}{1+R}(1-\cos\alpha) \qquad (81\text{A})$$

This is slightly different from equation 81, and is equivalent to Johannessen's equation 10. The solution to equation 81(A) is

$$N_g\varphi_n=1/2(E_s+E_c/N)(1-\cos\alpha)-\frac{\Delta E_cR}{1+R}\left[1-\left(\frac{R-1}{R+1}\right)^n\right] \qquad (91\text{A})$$

Note that the same characteristic equation is obtained from all of these different equations. It is possible to find the roots of the first-order difference equation without applying Nyquist's criterion.

The author thoroughly agrees that the mechanisms of gain and time constant are clearly implied in the difference equation for the amplifier. The principal objective of Part II was, in fact, to enlarge upon the difference equation, giving physical and graphical interpretation to its terms. The author solved the difference equation for a step function applied at the input. The resulting time constant and the static gain are used to construct the transfer function. Johannessen took the Laplace transform of the difference equation to obtain his equation 15. This is the more accurate expression for the amplifier transfer function. If the exponentials are replaced by means of the approximate equality, for signal frequencies much lower than that of the carrier

$$\epsilon^{-\frac{\pi}{\omega}s}\doteq\frac{1}{1+\frac{\pi}{\omega}S}$$

Johannessen's equation 26 results directly

$$G(S)=\frac{R/N\left(1+\frac{\pi}{2\omega}S\right)}{1+\frac{\pi}{2\omega}(1+R)S}$$

The assumption made that signal frequencies are much lower than the carrier states that the numerator time constant is insignificant in the range for which the expression is valid. For any value of R, the derivation of the author's equation 92 requires the same assumption in order to represent the exponential by the first two terms of the Taylor series. Ignoring the author's delay term and retaining the $1+R$ from equation 92, one finds that the two results are the same and are based on the same approximations. Both yield the same gain-bandwidth product. At frequencies where the delay is important, or where the approximation by the transfer function of a continuous-data system becomes inadequate, other factors become important. The output is defined as an impulse function appearing at the end of the nth half-cycle. Since we are interested in the system viewpoint, it will be necessary in such cases to determine whether the load will wait until the end of the half-cycle to begin its response.

With the square waves assumed by Ringelman and Fenaroli (see reference 2 of Mr. Bourne's discussion), the solution of the difference equation becomes

$$N_g\varphi_n=\frac{E_s}{2}(1+E)\alpha-\frac{\Delta E_cR\pi}{2N}\left[1-\left(\frac{R-1}{R+1}\right)^n\right] \qquad (97$$

Either this equation or equation 91, or equation 91(A), predict an oscillatory response to a step of input for $R<1$, because of the alternating sign of the factor raised to the nth power. The oscillatory response can also be easily shown from Fig. 16. One can equate this to the integral of the discharging voltage between zero and the firing time t_n. The firing time is found without the requirement that the transient begin with zero output.

$$t_n=\frac{2}{\omega E_s(1+E')}N_g\varphi_n \qquad (98)$$

For the simplified case of zero initial output

$$t_n=t_0\left\{1-ER\left[1-\left(\frac{R-1}{R+1}\right)^n\right]\right\} \qquad (99)$$

which is equal to equation 16 of the reference. For the sine wave of supply voltage and rectified-sine-wave control

$$\cos\omega t_n=1-\frac{2}{E_s(1+E')}N_g\varphi_n \qquad (100)$$

which can be expanded in terms of equation 91(A) to give similar results.

In mode II, inspection of the graph corresponding to Fig. 17 gives the difference equation

$$N_g\varphi_{n+1}-\left(\frac{E'R-1}{E'R+1}\right)N_g\varphi_n=-\frac{2\Delta E_cR}{N(1+R)}+\frac{2E_s}{1+R}(1-\cos\alpha) \qquad (101)$$

This is the first-order difference equation with a nonconstant coefficient. The solution for a step of input voltage is

$$N_g\varphi_n=\frac{E_s(1+ER)}{1+R}(1-\cos\alpha)-\frac{\Delta E_c}{N}\left(\frac{R}{1+R}\right)(\cos\alpha'+\cos\alpha)\times\left[1-\left(\frac{E'R-1}{E'R+1}\right)^n\right] \qquad (102)$$

The author strongly recommends that the reader examine and corroborate the results of the various references. One additional reference is listed with two supplementary references on the origin, properties, and solution of difference equations.

Direct-Water-Cooled Germanium Power Rectifier

R. E. WAHL
ASSOCIATE MEMBER AIEE

SINCE THE DEVELOPMENT of large-area germanium rectifier cells in 1952, over 20,000 kw of d-c power have been installed and are in service. An equally large amount of germanium rectifier units for converting alternating current to direct current are on order with the various manufacturers of this type of equipment. The first commercial germanium rectifier units used a germanium rectifier stack as shown in Fig. 1. The germanium rectifier cell was sealed with lacquer, making it partially impervious to moisture and atmosphere. This stack was then immersed in a tank containing perchlorethylene and connected with other stacks to form a number of 3-phase bridge rectifiers. The tray was then cooled by running tap water through a thin copper tube surrounding the germanium rectifier stacks. Later, the germanium rectifier stacks were installed in a tank and the perchlorethylene recirculated through several tanks and a water-to-perchlorethylene heat exchanger, to remove the losses from the germanium rectifier stacks. A recent tray using this construction is shown in Fig. 2 which forms part of a 65-volt d-c unit at 15,000 amperes.

During this time, work was going on to develop a hermetically sealed germanium rectifier cell. This construction, shown in Fig. 3, uses a metallized ceramic insulator of alumina. This development led directly to air-cooled hermetically sealed germanium rectifiers such as shown in Fig. 4, and to direct-water-cooled rectifier units, which is the subject of this paper.

Germanium Rectifier Cell

The heart of the rectifier is a small wafer of ultrapure single-crystal germanium which is sandwiched between an acceptor solder on one side and a donor solder on the other. Germanium is a semiconductor, which means that the material is neither a good conductor nor a good insulator. The atomic bonds of germanium atoms are readily broken by thermal agitation and some conduction occurs at room temperature, increasing greatly at temperatures over 100 C (degrees centigrade). Of much greater importance than these temperature effects is the asymmetrical conduction caused by impurities in the germanium crystal structure. Atoms with 5-valence electrons, such as phosphorus, arsenic and antimony, can enter the crystal-lattice in place of germanium atoms. Here four of the five electrons will enter the inner atomic bonds, the fifth electron being bound by only the slight electric charge on the nucleus. At room temperature, thermal agitation is sufficient to free these extra electrons so that they can wander through the lattice and conduct current. This is called *n*-type conduction (*n* for negative). Because these impurities provide conduction electrons, they are called donors.

If impurities such as boron, aluminum, gallium, and indium, are used, whose atoms have only 3-valence electrons, they produce so-called *p*-type conduction (*p* for positive) when they enter the crystal-lattice. Around each of these atomic impurities the structure will be locally incomplete, forming a trap for one more electron. An electron from a near-by bond can then jump into this trap, leaving a vacancy, or hole, behind. Another electron can migrate into the resulting vacancy, and so on in the process. This migration of electrons allows the hole to wander effectively about the lattice and in so doing to conduct electricity. This *p*-type conduction is in a direction opposite to that of electrons and is produced by impurities that are called acceptors.

In Fig. 3, then, the lower surface of the germanium alloyed with arsenic, a donor, produces *n*-type material, while the upper surface alloyed with indium produces *p*-type material in the same crystal. The junction between the *n* type and the *p* type is called a P-N junction. A P-N junction has a rectifying property, in that an electric current flows through it in one direction with ease but with great difficulty in the other direction. If the *p* region is made positive and the *n* region negative, holes and electrons are driven toward each other and recombined, each electron filling up one hole. The voltage required for this is low, being only enough to keep the current going. This is the forward direction or easy-flow direction of current. If the *p*-type region is made negative with respect to the *n*-type region, the electrons and holes move away from each other leaving the region close to the junction an insulator since it has no current carriers. This region is called the barrier layer. The inversely biased P-N junction, however, will conduct electricity in the inverse direction if carriers are introduced. Carriers are actually induced thermally by the breaking of bonds in the germanium which supplies conduction electrons and holes. This constitutes reverse current, also known as leakage current or saturation current. The remainder of the structure shown in Fig. 3 provides protection of the germanium rectifier junction against mechanical damage, moisture, and atmospheric conditions. It also provides a means for connecting electrical terminals to the device as well as a means for removing the heat generated by the forward current and the reverse current flowing through the junction.

Direct-Water-Cooled Germanium Rectifier Stack

The development of the hermetically sealed germanium rectifier cell made direct water-cooling of it possible. This complete rectifier stack is shown in Fig. 5. The construction enables the rectifier stack to be cooled by means of water flowing between the seven projections on one side of the stack. Fig. 6 shows these projections with a Buna N rubber gasket to seal one surface of the stack when mounted, as shown in Fig. 7. In a close-up view, Fig. 8, shows the rectifier stack mounted to a short section of stack support. Water flowing through this stack support flows past the projecting pins and removes heat generated by the rectifying junction in a very efficient manner. This is shown in Fig. 9, which is a plot of cell rise versus watts dissipated in the junction. It shows approximately 1/4 C rise per watt dissipated in the junction. Other structures may exhibit as high as 1 C rise

per watt or higher. This curve was run experimentally by causing a direct current to flow through the rectifying junction in the forward direction and measuring d-c volts and d-c amperes across the stack. The cell temperature rise was measured by having a thermocouple imbedded in a small hole located a few thousandths of an inch away from the rectifying junction.

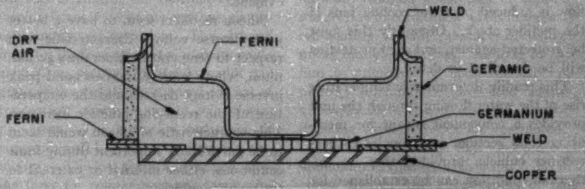
Further tests show that this method measures the junction temperature to within about 2 C below the actual junction temperature. This was determined by a plot on semilog paper of saturation current versus junction temperature with the rectifier stacks in a temperature-controlled oven. Here, the temperature of the junction is known, since the thermal gradient between the junction and the measuring point is zero, after the stack has reached constant temperature of oven and since no internal losses are present in the stack. This curve, then, was used with the stack mounted on its stack support and a plot was made of watts dissipation in the junction versus thermocouple temperature and temperature by saturation current.

To ensure that sufficient time was allowed between points on the foregoing curves, the thermal time constant of the rectifier stack was determined experimentally, as shown in Fig. 10. This indicates a thermal time constant of about 30 seconds, the point at which the junction has reached 63.2% (per cent) of its final steady-state temperature rise. Thus, in five time constants or about 2½ minutes, the junction will have reached its steady-state temperature rise to better than 99%.

The static d-c characteristic of a cell is shown in Fig. 11, which shows a forward voltage drop of approximately 0.6 volt at 83⅓ amperes direct current. This corresponds to approximately a 50-watt forward loss, while the reverse losses constitute an additional 20%, making a total of approximately 60 watts in the junction to be dissipated. It is the removal of this 60 watts from the germanium wafer that constitutes the major problem in spite of its being a small amount of power. This is one of the main reasons that the principle of direct water cooling was developed, eliminating, as it does, as many interchanges of heat between the rectifying junction and the coolant which finally removes the heat generated. Limiting the junction temperature to below 100 C, which is a maximum permissible temperature, requires that the junction then be cooled with a reasonable engineering safety factor to about 65 C maximum. This means that if the stacks are to be cooled by a maximum water temperature of 35 C, which is permitted to rise 5 C as it goes through the series of rectifier stacks connected to the stack support, the remaining difference of 25 C is all that can be allowed for the rise of the junction above water at any one point.

Fig. 2. Model no. 6RA13DW1 germanium rectifier tray rated 1,667 amperes, pumped perchlorethylene-cooled, containing 20 6RA3-type rectifying devices and mounting current-limiting fuses and triggers. Outside view

The efficient removal of heat from the rectifier stack is, among other things, a function of water velocity past the projecting pins, shown in Fig. 12. This curve shows that at about 3 gpm (gallons per minute) with three extrusions connected in parallel, cells are cooled to within approximately 2 C of what they will be for an infinite water velocity through the cooling surfaces. Fig. 13 shows the temperature rise of water



HERMETICALLY SEALED GERMANIUM RECTIFIER CELL

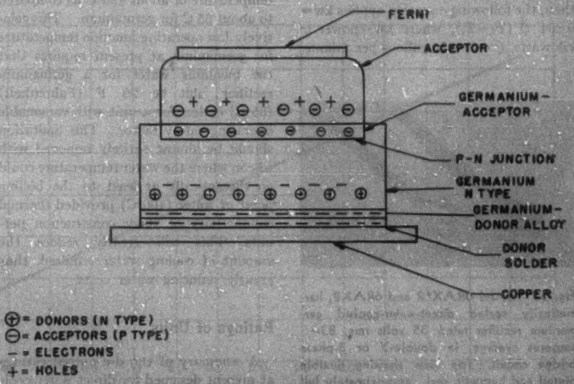


Fig. 3. Enlarged cross section of germanium rectifier cell

Fig. 4. Model 6RA14 (A-D) B4 hermetically sealed forced-air-cooled germanium rectifier, rated up to 65 volts rms, 83-$^1/_3$ amperes average, in double-Y or 3-phase bridge circuit; 7-fin design for reduced velocity cooling

flowing through three of the cooling extrusions in parallel versus gallons per minute of water. This curve shows that at about 3 gpm of water the temperature rise in the water is about 3 C. Since temperature rise of the water is inversely proportional to the rate of flow of water, the water rise would be 6 C at 1$^1/_2$ gpm. At one half of this flow, or 3/4 gpm, the temperature rise of the water would be 12 C. From this and the appearance of the curve it is apparent that a runaway condition exists for both the cooling water and the rectifier junction, as water flow is reduced past the cooling pins of the rectifier stack. Obviously this must be protected against, and such protection will be described in detail.

This readily determinable temperature rise of the water flowing through the unit provides a convenient means for measuring total rectifier junction losses in a rectifier cubicle, provided that an isothermal condition can be established for the stack supports. This can be done by having the average water temperature going through the unit equal to ambient in which the unit is immersed. Here, then, the following equation applies kw = 0.264 Q $(T_2 - T_1)$, where kw = power in kilowatts, Q = flow in gallons per minute, T_2 and T_1 = outlet and inlet temperatures in degrees centigrade. The temperature difference may be determined accurately by using relatively cool water and permitting a relatively large temperature rise in the water, since quantity of water may be measured accurately by flow into a standard volume container over a given length of time or by use of a precision flow-indicating device.

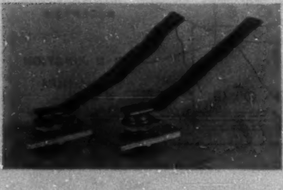

Fig. 5. Model 6RAX12 and 6RAX8, hermetically sealed direct-water-cooled germanium rectifier rated 65 volts rms, 83-$^1/_3$ amperes average, in double-Y or 3-phase bridge circuit. Top view showing flexible pigtail and hermetic seal; approximately full size

Silicon rectifier stacks can be applied directly to this type of direct water cooling by a simple substitution of the silicon rectifier for the germanium rectifier. At present, the highest current rating for a silicon rectifier is about 50 amperes average. Fortunately, silicon cells can be produced with considerably higher peak inverse voltage capacity so that while the forward current loss per cell is approximately twice that for germanium only one-half or fewer silicon rectifier cells will be required for higher voltage units than in the present germanium rectifier units. This means that for voltages above about 80 volts direct current, where two or more germanium rectifiers are required in series, the value of the silicon rectifier will be self-evident.

Silicon rectifiers seem to have a better peak inverse voltage characteristic with respect to temperature than does germanium, whose leakage increases and peak inverse voltage decreases as the temperature of the rectifying junction increases. This characteristic of silicon would seem to be particularly important during fault conditions, either internal or external to the rectifier cubicle.

The major advantage of silicon over germanium appears to be a considerably higher permissible operating junction temperature of about 150 C as compared to about 65 C for germanium. This relatively low operating junction temperature for germanium at present requires that the incoming water for a germanium rectifier unit be 95 F (Fahrenheit) (35 C) or less for a unit with reasonable operating safety factor. This limitation should be almost entirely removed with silicon where the water temperature could go theoretically at least to the boiling point of water (100 C) provided thermal conductivity of stack construction permits. This will greatly reduce the amount of cooling water required, thus greatly reducing water costs.

Ratings of Units

A summary of the d-c output ratings at present designed for direct water cooling is as follows:

Steel-mill rated units
- 100% rated output continuous
- 125% rated output ADC (amperes direct current) (2 hours)
- 150% rated output ADC (1 minute)
- 12, 15, 20, 25, 30 VDC (volts direct current) at 4,000, 5,000, 7,500 ADC

Electrochemical or metallurgical with transformer in rectifier cubicle
- 100% rated output continuous
- 150% rated output ADC (one minute)
- 50, 65, 75 VDC at 2,000, 2,500, 3,000, 4,000, 5,000 and 6,000 ADC
- 100, 130, 150 VDC at 1,000, 1,500, 2,000, 3,000 ADC

Electrochemical or metallurgical power supplies with transformer external to rectifier cubicle
- 100% rated output continuous
- 150% rated output ADC (one minute)
- 50, 65, 75 VDC at 8, 10, 12, 14, and 16 kilo-ADC
- 100, 130, 150 VDC at 5, 6, 7, 8, 10, 12, 14, 16 kilo-ADC

This listing shows units with a kilowatt output rating from 48 to 225 covering a voltage range from 12 to 30 volts direct current. These units use circuit number 49 in the ASA standard.[1] The wye primary on the transformer has a shifting neutral which provides 120-degree cell conduction in the rectifying elements. This circuit permits elimination of the interphase transformer used in circuit 45 in the same standard, thereby eliminating its losses and regulation. However, a corresponding change in transformer design must be dealt with.

The electrochemical units use either circuits 23, 24, 25, or 26 in the foregoing standards with kilowatt ratings from 100 to 450, where the transformer is included in the rectifier cubicle. This type of unit is preferred where a double voltage transformation is desirable as, for example, where an existing substation providing one of the standard voltages up to about 600 volts is already available. Ratings of units from 400 to 2,400 kw output power can be obtained in a single cubicle which uses a transformer external to the rectifier cubicle. This type of unit is desirable when it is more economical to use a single

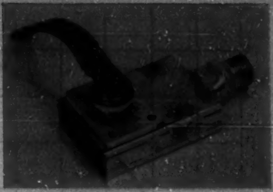

Fig. 8. Model 6RAX8, hermetically sealed direct-water-cooled germanium rectifier rated 65 volts rms, 83-1/3 amperes average, in double-Y or 3-phase bridge circuit. View showing rectifier in position; hollow, water-cooled bus bar

magnetic voltage conversion from a-c power systems of 2,400 up to about 15,000 volts. This type of installation is more economical in large power installations and where a new installation is being made.

The higher voltage electrochemical units, i.e., 100-, 130-, or 150-volt direct current, use two germanium rectifier stacks in series to provide sufficient inverse voltage rating. While the lower voltage units, i.e., 50-, 65-, and 75-volt d-c, can be put into series to provide 100-, 130-, and 150-volt direct voltages and higher, it is more economical to series stacks mainly because of savings in bus conductors carrying a-c power to the rectifying stacks. Some savings also accrue because the d-c outputs in the series stack units are essentially one output and need not be tied in series.

While the chart does not show units rated higher than 150 volts direct current, these units may be connected in series to get up to 600 volts direct current until such time as higher direct-voltage units are designed. Further experience with the presently designed units is required before voltage may be extended beyond this.

Electrochemical Problems

Because aluminum is basically less expensive as a current-carrying part than copper, considerable effort was devoted to making the stack support and germanium cell holder out of this element. It was found that the stack support could be an aluminum extrusion and the cell holder a die casting. It also became evident that the prevention of corrosion of these aluminum parts was extremely difficult because of their contact with water.

The main problem in using aluminum parts is to control the thermal-dynamic driving forces so as to prevent any significant amount of corrosion. This driving force for the formation of aluminum oxide at 25 C approaches 7,000 calories for one gram of the metal as compared to that of copper into cuprous oxide of 300 calories per gram. The corrosion resistance of copper is well known, as is that for aluminum. The low thermal-dynamic driving force for copper accounts for its inherent inactivity, but certainly does not account for aluminum's apparent inactivity.

Oxide Film

The invisible oxide film which forms on aluminum at room temperature has made possible the use of aluminum for high-voltage transmission-line cables since the turn of the century; its use also includes aluminum storm windows, entire building facades, entire aircraft fuselage and wing structures, as well as the commonplace aluminum pots and pans. This naturally formed oxide film is approximately one micron thick. It is inherently self-healing in the presence of oxygen under many conditions. As long as this film is unbroken or spontaneously repaired, aluminum is protected against atmospheric corrosion, and the thermodynamic driving forces are restrained.

This invisible oxide film also protects aluminum in contact with water. To increase further the effectiveness of this oxide film, the aluminum may be anodized by an electrolytic process which builds up this film up to about one mil in thick-

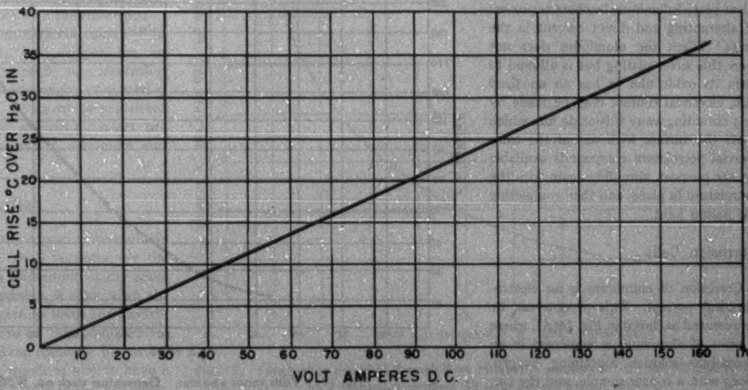

Fig. 9. Volt-amperes versus cell rise degrees centigrade above H_2O ambient 4.5 gpm H_2O, series tubes germanium stack no. W56

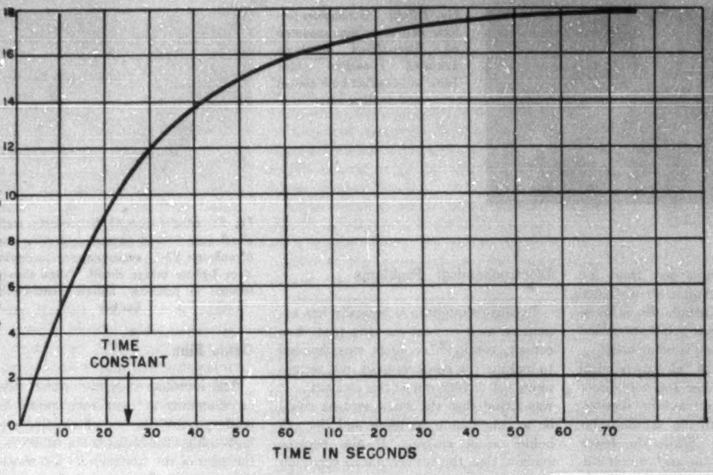

Fig. 10. H_2O-cooled germanium 6RAX8. Thermal time constant. Thermocouple in drilled hole in cell

ness. This aluminum oxide, however, is a semiconductor and has a relatively high resistance to the flow of current. Because of this it is desirable to make electric connections to the aluminum where the anodic film has been removed or prevented from forming, or to use another type of surface protection which provides good electrical conductivity.

In the past few years, the quality and cost of silver-plating aluminum surfaces has been greatly improved and it can now be used to restrain the thermodynamic driving forces and also to provide an electrical contact surface to the aluminum. Several large installations of metallic rectifiers have been in operation for years using silver-plated aluminum bus bars as carriers of alternating and direct current in the units. When the aluminum does not have this silver plating but is allowed to form its oxide film or has an anodized film, electrical contact may be made by first abraiding away this oxide film which coats the surface with one of the commercial petrolatum compounds available for the purpose, abraiding again with the petrolatum in place, and then completing the bolted joint.

Corrosion Cells

Corrosion of aluminum is an electrochemical process. This process can be represented as shown in Fig. 14(A), where a piece of aluminum is immersed in an electrolyte solution containing oxygen, along with a copper sample, and the two are connected together electrically. In this case, the aluminum corrodes proportional to the number of electrons which flow from the aluminum to the copper in the external circuit. The electrode reactions are shown for both the anode and cathode in Fig. 14.

In the foregoing example it would be easy to stop corrosion of the aluminum by merely disconnecting the two from one another electrically. Unfortunately, this is not the usual case, and anodes and cathodes may occur as shown in Fig. 14-(B). Here, copper has been deposited onto aluminum and corrosion results, as shown, with the same anode and cathode reactions taking place. This action causes the metal to corrode in spots, and it is this localized corrosion which causes the most trouble, since it may lead to perforation. Fortunately, the oxide film may build up in the corroded areas and prevent perforation, and the inevitable leakage of electrolyte would follow.

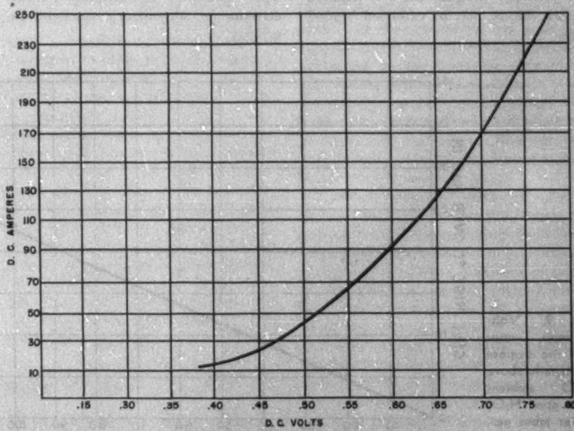

Fig. 11. Volts versus amperes. Germanium stack no. W56

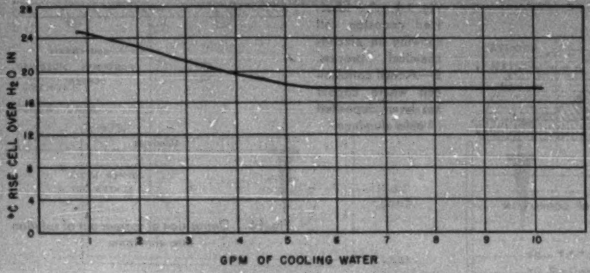

Fig. 12. Cell temperature rise versus gpm coolant

This localized attack of aluminum can be expected when the following four requirements are satisfied:

1. A cathode reaction can take place in conjunction with the anodic oxidation of aluminum, which can give rise to an electromotive force.
2. An electrolyte joins anode and cathode.
3. Anode and cathode are in metallic contact.
4. The natural oxide film on aluminum is broken or destroyed and a protective film cannot reform.

Fig. 15 shows the results which follow when aluminum and copper are joined so as to meet these four requirements. Here corrosion could have been prevented by keeping the joint dry or preventing moisture from gaining entrance to the junction by a suitable coating. Where moisture is unavoidable, corrosion may be prevented by measures which prevent copper from being transferred to the aluminum. This occurs as shown in Fig. 16. The best way to prevent this, of course, is not to have copper in the electrolite or in contact with the electrolite.

Fig. 17 shows another corrosion cell in which aluminum and copper are in metallic contact with an electrolite between them which results in corrosion of the aluminum. This can be prevented by removing the electrical contact between the two elements, aluminum and copper.

Cathodic Protection

In Fig. 16(A) the copper is the cathode and is protected from corrosion by the corroding of the aluminum in the same electrolyte. Corrosion is always at the anode, where electrons leave the electrolite. Metallic ions at this point are released into solution resulting in rusting or pitting. The anode is said to have a higher solution potential than the cathode, i.e., a greater tendency to go into solution. This can be illustrated quickly by the experiment shown in Fig. 18, where a silver coin is connected through a milliammeter to a nail. Here the nail will act as an anode, the current will flow, and a rust cloud will appear surrounding the nail. The silver coin is cathodic and is said to be cathodically protected. In this case, the nail gradually erodes away and is said to be sacrificial. The milliammeter indicates a galvanic current flowing.

If this galvanic current can be neutralized, overcome, or stopped by an equal or greater flow of current in the opposite direction, then the anodic areas of the metal to be protected become cathodic to the auxiliary anodes. This is shown in Fig. 19, where two identical nails are suspended in an electrolyte and connected to an external battery. The nail connected to the positive terminal of the battery is the anode, and a rust cloud soon appears surrounding it in the solution. The other nail connected to the negative terminal of the battery is cathodically protected.

Frequently it is not desirable to have an anode which is sacrificed since it may contaminate the electrolyte. This contamination can be prevented by using in place of a sacrificial anode a permanent, nonsacrificial anode made of a platinum wire or a stainless steel rod clad with platinum foil. This functions as follows, when oxygen ions are attracted to the positive or anodic terminal where they are released but can combine chemically with an iron anode to form oxide or rust. If a platinum wire or terminal is used for the anode, the rust cloud disappears because there is no longer any chemical union of oxygen with the metal and the anode, thus the platinum remains permanently and is nonsacrificial. Hydrogen is released at the negative or cathodic terminal, and does not join chemically with the cathode but rises as bubbles to the surface. Fig. 20(B) shows how a permanent nonsacrificial anode made of platinum may be used to protect an aluminum shell when a difference in potential is applied between the platinum anode and the aluminum shell.

In this project, then, the main methods used to prevent corrosion of the aluminum extrusion were the use of cathodic protection for over-all protection of the parts, and the use of surface films as described to prevent local action, as shown in Figs. 21 and 22. The combination of

these two methods of protection where reasonable care is taken to prevent breakage of the protective surface film provides excellent corrosion resistance to waters having pH values between about 4.5 and 8.5. The presence of chlorides, particularly in conjunction with heavy metal ions, is generally deleterious and is also prevented by separation of these two components electrically. This separation of heavy metal ions from the aluminum could be provided to as great an extent as possible by having fluid control elements separated from the aluminum extrusion by lengths of polyvinyl chloride plastic pipe.

Tap water can usually be used directly with this type of unit provided the pH is within the limits as previously specified and its minimum resistivity is 2,000 ohm-centimeters. Tap water here means drinking water. Pure water, of course, can be used where satisfactory tap water is not available. This requires the use of an auxiliary water-to-water heat exchanger with the pure water being recirculated as a coolant for the germanium rectifier elements. Pure water is generally meant to be distilled water, steam condensate, or deionized waters and should have a resistivity equal to or better than 30,000 ohm-centimeters. Whenever there is a question as to the suitability of available cooling water, the recirculating system should be used with periodic resistivity measurements being made on the pure water side.

Because water supplies may vary considerably from locality to locality and from time to time it was decided to use copper stack supports and cell holders. Direct water-cooling is permissible where chloride content, heavy metal ions, pH and solids are below American Standards Association limits. If these limits are exceeded a closed recirculating system is required. Protection for these copper parts is required against anodic corrosion with the use of either nonsacrificial platinum anodes (or targets, as they are called) or stainless steel anodes which very slowly erode away.

Transformers

Transformers are of relatively standard design. In general, the two types of transformers available are AIEE standard classification of insulating material class *B* and class *H*. The class *B* is in general standard but the class *H* can be supplied where severe moisture conditions are likely to occur in the application of the rectifier units. The hottest-spot temperatures are for class *B*, 130 C (266 F) and for class *H*, 180 C (356 F). The transformers with class *H* insulation are better for heavy duty, where overloads may be encountered. The additional 50 C design rating with class *H* has over class *B* may be used to provide longer transformer service or reduction of weight of unit. The cores used in the 3-phase power transformers are grain-oriented silicon steel assembled into a core-type transformer. This grain-oriented steel has high saturation flux density, and lower core losses and exciting volt-amperes than were previously available from regular silicon steel. These characteristics enable operation at higher inductions with subsequent reductions in core cross section and hence weight of transformer. Each silicon steel strip is treated on both sides with a modified high-temperature coating which provides exceptionally good interlamination resistance with a negligible effect on space factor.

Transformer windings are form-wound on arbors of the proper size, insulated, and braced to withstand the mechanical stress between the current-carrying conductors because of overloads or short circuits on the rectifier units. The primary windings are of conventional construction with the use of copper or aluminum as the current-carrying part. Secondaries are of an improved design based on strip copper or strip aluminum wound spirally. This design is especially suitable where heavy d-c winding currents are required on a transformer kva basis as compared to the usual design of power transformers. The aluminum or copper strip is almost a complete length of the transformer core window with provision for proper yoke insulation requirements being met. High space factors are maintained on the d-c windings by using a Mylar polyester film

bonded to highly purified asbestos, which provides the great mechanical strength required as well as high electrical breakdown characteristics.

Transformers are normally checked for ratio, polarity, and phase relations, no-load loss, exciting current, load loss, impedance, dielectric tests (1. applied potential, and 2. induced potential), and temperature rise on one unit of a new design. Other special tests which may be run where required by customers are temperature rise on duplicate units, impulse test, noise level test, zero sequence impedance test, and insulation power factor test. Each transformer also has an overtemperature thermoswitch imbedded in its center leg near the estimated hot-spot point in the winding to provide protection against short circuits and excessively long overloads which might cause winding insulation to deteriorate more rapidly than is desired.

Class *B* transformers are insulated with a general-purpose clear baking varnish with a phenolic drying oil base. The complete transformer is vacuum-impregnated to provide proper surface coating, and filling of spaces in porous insulation and interstices between copper turns; to build up film insulation upon conductors, coils, and coil assemblies; and to bond coils and coil assemblies together for additional electrical and mechanical strength. Class *H* transformers use silicon resin as the insulating varnish. The use of silicon varnish improves most of desired characteristics mentioned in the foregoing.

Protection of Units

Rectifier units are normally protected against d-c short circuit, rectifier cell failure, coolant overtemperature, loss of coolant, minimum flow, voltage surges detrimental to germanium cells and d-c overload. D-c short-circuit protection is provided but, in general, germanium rectifier applications are limited to loads where d-c short circuits are extremely unlikely or impossible. This protection is provided by a-c circuit breakers coordinated with d-c overload protective devices. Instantaneous breaker trip elements are set down to approximately four times the a-c rating of the rectifier unit. Air circuit breakers are, in general, used for units of this type, their particular selection being determined by circuit voltage and interrupting rating required, and load current-carrying capacity.

A small percentage of germanium rectifier cells fail in such a manner that they lose their ability to prevent the flow of current in the reverse direction and become essentially short circuits. Protection against this is provided by high-speed fuses that can withstand less I^2T than the germanium rectifier cell, thus providing protection for good cells against possible short circuit of any potentially defective cell. This type of protection is similar to arc-back protection required in mercury arc rectifiers.

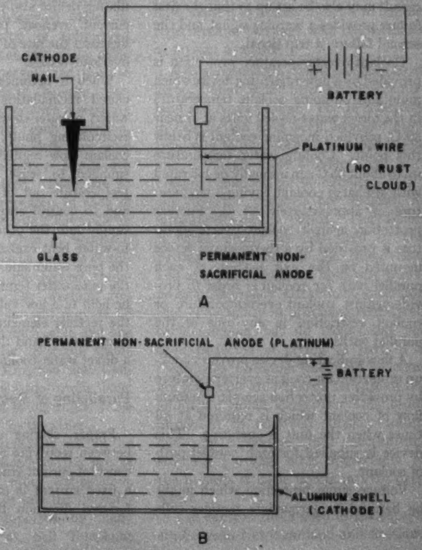

Fig. 20. A—Nonsacrificial anode cathodically protects nail. B—Permanent nonsacrificial anode (platinum)

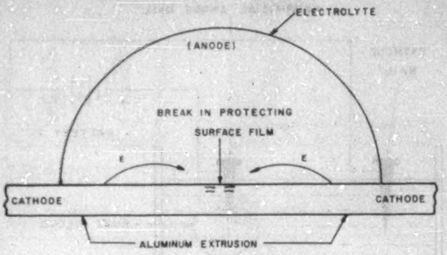

Fig. 21. Corrosion at break in surface

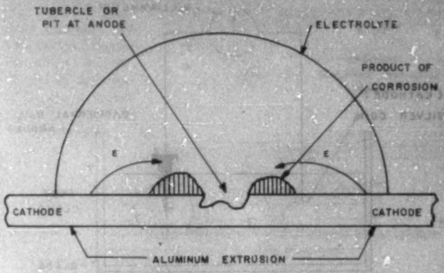

Fig. 22. Pitting attach, result of corrosion at break in surface

The use of these germanium power fuses necessitates some type of monitoring system for these fuses. If such a system were not provided, loss of some of the rectifying elements could cause loss of additional rectifying elements. In the early stages of development of this type of germanium rectifier unit a solenoid-operated stepping relay was used to check each fuse at regular intervals and to provide either a trip or warning signal when a burned fused was discovered. Another type of fuse-monitoring circuit consists of fuses connected across the main fuses. When the main fuse burns, the trigger fuse also burns and releases a plunger which closes a signal circuit which may be used either to warn or to trip. This circuit may also be set up so that the first failure provides a warning signal, and the second failure, a trip signal.

Coolant overtemperature protection is provided by a flow-regulating device which maintains outgoing coolant temperature in the direct water-cooled units at or near 30 C, provided incoming coolant is below this point. Cooling water temperature up to about 35 C can normally be tolerated with discharge coolant having a temperature of approximately 40 C. Further protection against coolant overtemperature is provided by a thermostatic device mounted on the exit portion of each parallel path for coolant in order to provide against coolant overtemperature or coolant restriction in any one of the parallel paths.

A flow-indicating device provides back-up protection for coolant overtemperature by providing protection against minimum flow of coolant which is required at all times when the unit is operating. This device is supplied for each parallel path of coolant.

Voltage surge protection which might be harmful to germanium rectifier cells is provided by Thyrite resistors and surge suppression capacitors connected as mentioned previously. These protect against a-c power supply surges, d-c circuit induced surges, and internally produced surges.

D-c overload protection is provided by standard commercial induction disk-type relays or plunger-type relays. The particular type of relay selected is determined by the nature of the d-c load and whether overload characteristics are required. For example, a d-c load may require 125% d-c load current for one minute or even 150% d-c load current for one minute. This requires proper co-ordination between all of the protective devices involved in the system. The flow-regulating device also provides a measure of current overload protection in that it increases the rate of coolant flow when an overload occurs.

When it becomes necessary to use a closed recirculating system with pure water, a water-to-water heat exchanger, recirculating pump, and reservoir with coolant flow regulator will normally be supplied to sense pure water coolant temperature out of the heat exchanger and to control entry water from water supply into the other side of the water-to-water heat exchanger. Since flow on the pure water side is at a constant rate, the pure-water temperature gradient can be held to a low value, thus maintaining the rectifier elements within a narrower temperature band than can be done with a direct water-cooling system.

Paralleling of Rectifier Cells

Proper sharing of the load current between rectifying cells is provided by a constant-current grading method in which a fixed current is caused to flow in the forward direction through the rectifier element, and the voltage drop across the cell and its supporting structure is measured. Installation of rectifier cells in groups having a voltage drop within a very narrow band ensures that each rectifying cell will be carrying its proper amount of load current. Cells are also graded in accordance with their peak inverse voltage characteristics to ensure their being operated properly on the particular circuit and the particular voltage rating in which they are being used.

Regulation of D-C Output

Two types of direct voltage control can normally be provided since germanium rectifier units cannot be regulated by phase control as mercury arc rectifiers can be. Induction voltage regulators or saturable reactors are the two common types. Saturable reactors provide a faster response in general than do induction voltage regulators or the rather infrequently used tap-changing transformer control, the latter being of either the no-load or on-load type.

Improvements

Major improvements accomplished by this design are ease of cell replacements, reduction of cost per kilowatt output and inertness to chemical atmospheres. Rectifier cells can be replaced readily by unbolting four bolts holding the rectifier stack in place on its cooling tube. The cost per kilowatt has been reduced drastically by the new design which reduces floor space required on most of the units as well as providing improved cooling for rectifier junctions, thus providing longer life. Some of the transformerless units have almost 10 kw output per cubic foot of volume occupied and up to 60 kw per square foot of floor space required. The units incorporating transformers show smaller kilowatts per cubic foot and per square foot. Protection against chemical atmospheres is provided for the germanium rectifier cells by its own hermetic seal which is part of its basic structure.

Transatlantic Communications: A Historical Résumé

MERVIN J. KELLY SIR GORDON RADLEY

THE PAPERS that follow describe the design, manufacture, and installation of the first transatlantic telephone cable system in all its component parts, including the connecting microwave radio-relay system in Nova Scotia. The purpose of this introduction is to set the scene in which this project was undertaken and to discuss the technical contribution it has made to the development of world communications.

Electrical communication between the two sides of the North Atlantic started in 1866. In that year, the laying of a telegraph cable between the British Isles and Newfoundland was successfully completed. Three previous attempts to establish transatlantic telegraph communication by submarine cable had failed. These failures are today seen to be the result of insufficient appreciation of the relation between the mechanical design of the cable and the stresses to which it is subjected as it is laid in the deep waters of the Atlantic. The making and laying of deep-sea cables was a new art and designers had few experiments to guide them.

During the succeeding 90 years, submarine telegraph communication cables have been laid all over the world. Cable design has evolved from the simple structure of the first transatlantic telegraph cable—a stranded copper conductor, insulated with gutta-percha and finished off with servings of jute yarn and soft armoring wires—to the relatively complex structure of the modern coaxial cable, strengthened by high-tensile steel armoring for deep-sea operation. The coaxial structure of the conducting path is necessary for the transmission of the wide frequency bandwidth required for many telephone channels of communication. The optimum mechanical design of the structure for this first transoceanic telephone cable has been determined by many experiments in the laboratory and at sea. As a result, the cable engineer is confident that the risk of damage is exceedingly small even when the cable has to be laid and recovered under conditions which impose tensile loads approaching the breaking strength of the structure.

The great difference between the transatlantic telephone cable and all earlier transoceanic telegraph cables is, however, the inclusion of submerged repeaters as an integral part of the cable at equally spaced intervals and the use of two separate cables in the long intercontinental section to provide a separate transmission path for each direction. The repeaters make possible a very large increase in the frequency bandwidth that can be transmitted. There are 51 of these submerged repeaters in each of the two cables connecting Clarenville in Newfoundland with Oban in Scotland. Each repeater provides 65 decibels of amplification at 164 kc, the highest transmitted frequency. The working frequency range of 144 kc will provide 35 telephone channels in each cable and one channel to be used for telegraph traffic between the United Kingdom and Canada. Each cable is a 1-way traffic lane, all the "go" channels being in one cable and all the "return" in the other.

The design of the repeaters used in the North Atlantic is based on the use of electron tubes and other components, initially constructed or selected for reliability in service, supported by many years of research at Bell Telephone Laboratories. Nevertheless, the use of so many repeaters in one cable at the bottom of the ocean has been a bold step forward, well beyond anything that has been attempted hitherto. There are some 300 electron tubes and 6,000 other components in the submerged repeaters of the system. Many of the repeaters are at depths exceeding 2,000 fathoms ($2^1/_4$ miles) and recovery of the cable and replacement of a faulty repeater might well be a protracted and expensive operation. This has provided the incentive for a design that provides a new order of reliability and long life.

On the North Atlantic section of the route, the repeater elements are housed in flexible containers that can pass around the normal cable-laying gear without requiring the ship to be stopped each time a repeater is laid. The advantages of this flexible housing have been apparent during the laying operations of 1955 and 1956. They have made it possible to continue laying cable and repeaters under weather conditions which would have made it extremely difficult to handle rigid repeater housings with the methods at present available.

A single connecting cable has been used across Cabot Strait between Newfoundland and Nova Scotia. The 16 repeaters in this section have been arranged electronically to give both-way amplification and the single cable provides "go" and "return" channels for 60 circuits. "Go" and "return" channels are disposed in separate frequency bands. The design is based closely on that used by the British Post Office in the North Sea. Use of a single cable for both-way transmission has many attractions, including that of flexibility in providing repeatered cable systems, but no means has yet been perfected of laying as part of a continuous operation the rigid repeater housings that are required because of the additional circuit elements. This is unimportant in relatively shallow water, but any operation that necessitates stopping the ship adds appreciably to the hazards of cable laying in very deep water.

The electron tubes used in the repeaters between Newfoundland and Scotland

are relatively inefficient, judged by present-day standards. They have a mutual conductance of 1,000 micromhos. Proved reliability, lower mechanical failure probability, and long life were the criteria that determined their choice. Electron tubes of much higher performance with a mutual conductance of 6,000 micromhos are used in the Newfoundland-Nova Scotia cable, and it is to be expected that long repeatered cable systems of the future will use electron tubes of similar performance. This will increase the amplification and enable a wider frequency band to be transmitted, thus assisting provision of a greater number of circuits. If every advantage is to be taken of the higher performance tubes, it will be necessary to duplicate (or parallel) the amplifier elements of each repeater, in the manner described in a later paper, in order to assure adequately long trouble-free performance. This has the disadvantage of requiring the use of a larger repeater housing.

During the 3 years that have elapsed since the announcement in December 1953, by the American Telephone and Telegraph Company, the British Post Office, and the Canadian Overseas Telecommunication Corporation, of their intention to construct the first transatlantic telephone cable system, considerable progress has been made in the development and use of transistors. The low power drain and operating voltage required will make practicable a cable with many more submerged repeaters than at present. This will make possible a further widening of the transmission band which could provide for more telephone circuits with accompanying decrease in cost per speech channel or the widened band could be utilized for television transmission. Much work, however, is yet to be done to mature the transistor art to the level of that of the thermionic electron tube and thus insure the constancy of characteristics and long trouble-free life that this transatlantic service demands.

The present transatlantic telephone cable whose technical properties are presented in the accompanying papers, however, gives promise of large reduction in costs of transoceanic communications on routes where the traffic justifies the provision of large traffic capacity repeatered cables. The thirty-six 4-kc channels which each cable of the 2-way system provides, are the equivalent of at least 864 telegraph channels. A modern telegraph cable of the same length without repeaters would provide only one channel of the same speed. The first transatlantic telegraph cable operated at a much slower speed, and transmitted only three words per minute. The greater capacity of future cables will reduce still further the cost of each communication circuit provided in them. Such considerations point to the economic advantage, where traffic potentials justify it, of providing broad-band repeatered cables for all telephone, telegraph, and teletypewriter service across ocean barriers.

The new transatlantic telephone cable supplements the service now provided by radio telephone between the European and North American continents. It adds greatly to the present traffic-handling capacity of this service. The first of these radio circuits was brought into operation between London and New York in 1927. As demands for service have grown, the number of circuits has been increased. We are, however, fast approaching a limit on further additions, as almost all possible frequency space has now been occupied. The submarine telephone cable has come therefore at an opportune time; further growth in traffic is not limited by traffic capacity.

Technical developments over the years by the British Post Office and Bell Telephone Laboratories have brought continuing improvement in the quality, continuity, and reliability of the radio circuits. The use of high-frequency transmission on a single side band with suppressed carrier and steerable receiving antenna are typical of these developments. Even so, the route, because of its location on the earth's surface, is particularly susceptible to ionospheric disturbances which produce quality deterioration and at times interrupt the service completely. Cable transmission is free of all such quality and continuity limitations. In fact, service of the quality and reliability of the long-distance service in America and Western Europe is possible. This quality and continuity improvement may well accelerate the growth in transatlantic traffic.

The British Post Office and Bell Telephone Laboratories are continuing vigorous programs of research and development on submarine cable systems. Continuing technical advance can be anticipated. Broader transmission bands, lower cost systems, and greater insurance of continuous, reliable, and high-quality services surely follow.

Transatlantic Telephone Cable System—Planning and Over-all Performance

E. T. MOTTRAM R. J. HALSEY J. W. EMLING R. G. GRIFFITH

Synopsis: The transatlantic telephone cable system was designed as a link connecting continent-wide communication networks on the two sides of the Atlantic. The technical planning of the system and the objectives set up so that this role would be fulfilled, are the principal subjects of this paper. Typical performance characteristics illustrate the high degree with which the objectives have been realized. Optimum application of the experience of the British Post Office with rigid repeaters and the Bell System with flexible repeaters, together with close cooperation among the administrations, have played a large part in achieving the objectives.

THE transatlantic telephone cable system was planned primarily to connect London to New York and London to Montreal, and thus serve as an interconnection between continent-wide networks on the two sides of the Atlantic. Thus, the system has to be capable of serving as a link in wire circuits as long as 10,000 miles, connecting telephone instruments supplied by various administrations and used by peoples of many nations. This role as an intercontinental link has, therefore, been a controlling consideration in setting the basic objectives for the system.

A Conference Paper presented at the Symposium on the Transatlantic Submarine Telephone Cable, during the AIEE Winter General Meeting, New York, N. Y., January 21–25, 1957.

E. T. MOTTRAM and J. W. EMLING are with the Bell Telephone Laboratories, Murray Hill, N. J., and New York, N. Y., respectively; R. J. HALSEY is with the British Post Office, London, England; and R. G. GRIFFITH is with the Canadian Overseas Telecommunications Corporation, Montreal, Que., Canada.

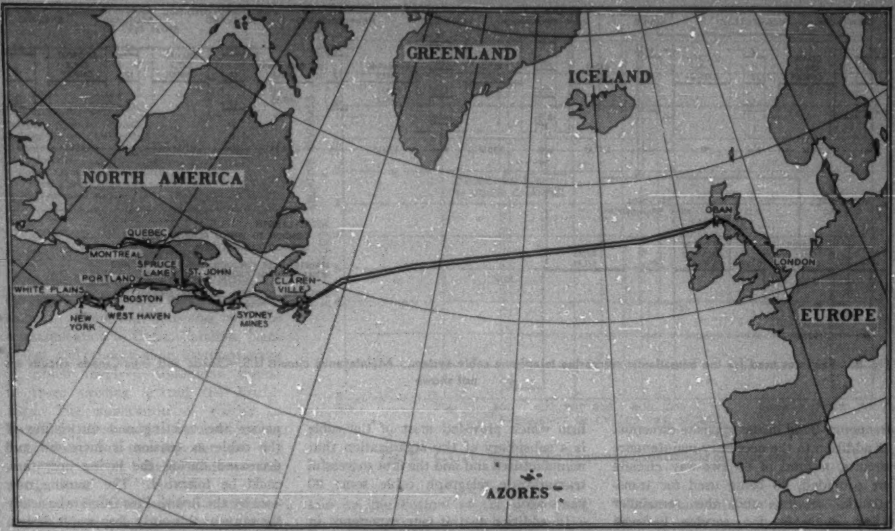

Fig. 1. Route of the transatlantic submarine telephone cable system

The end sections of the system utilize facilities which are integral parts of the internal networks of the United States, Great Britain, and Canada, but the essential new connecting links, extending between Oban, Scotland, and the United States-Canada border, and forming the greater part of the system, were built under an agreement between the joint owners, the American Telephone and Telegraph Company and its subsidiary the Eastern Telephone and Telegraph Company (in Canada), the British Post Office, and the Canadian Overseas Telecommunication Corporation. It is thus the joint effort of three nations.

In planning the system, the main centers of interest were, naturally, the two submarine cable sections, Scotland to Newfoundland, and Newfoundland to Nova Scotia, each of which had to meet a unique combination of requirements imposed by water depth, cable length, and transmitted bandwidth.

Over-All View of the System

The transatlantic system provides 29 telephone circuits between London and New York, 6 telephone circuits between London and Montreal, and a single circuit split between London-New York and London-Montreal; this split circuit is available for telegraph and other narrow-band uses. There are also 24 telephone circuits available for local service between Newfoundland and the mainland of Canada, and there is considerable excess capacity over the radio-relay link that crosses the Maritime Provinces of Canada.

A map of the system is shown in Fig. 1. The facilities used, together with the approximate route distances are shown in Fig. 2. It will be seen that the over-all lengths of the London to New York and London to Montreal circuits are 4,078 and 4,157 statute-miles respectively. Seven of the New York to London circuits are permanently extended to European continental centers; Paris, Frankfurt (two), Amsterdam, Brussels, Copenhagen, and Berne. The longest circuit is thus New York to Copenhagen, 4,948 miles.

Starting at London, which is the switching center for United Kingdom and continental points, 24-circuit carrier cables provide two alternative routes to Glasgow and thence to Oban by a new coaxial cable. Between London and Oban the two routes are fed in parallel at the sending ends, so a change-over can be effected at the receiving ends only. At a later date, an alternative route out of Oban will be provided by a new coaxial cable to Inverness.

From Oban a deep-sea submarine link connects to Clarenville, Newfoundland. This link is, in fact, two parallel submarine cables, one used for east-to-west transmission, the other for transmission in the reverse direction. Each cable is roughly 1,950 nautical-miles in length and lies at depths varying between a few hundred fathoms, on the continental shelf and to about 2,300 fathoms at the deepest point. Each cable incorporates 51 repeaters in flexible housings which compensate for the cable attenuation of about 3,200 db (decibel) at the top frequency of 164 kc (kilocycles per second). These cables carry 36 telephone circuits and maintenance circuits and establish the present maximum capacity of the transatlantic system.

At Clarenville, connection is made with Sydney Mines, Nova Scotia, by a second cable system which goes 63 statute-miles overland to Terrenceville, Newfoundland, and thence about 270 nautical-miles in coastal waters at a depth of about 250 fathoms. Although this system is partly on land, it is basically a submarine system in design, the two portions differing only in the protection of the cable. In this link, the two directions of transmission are carried by the same cable, a low-frequency band being used from west-to-east and a high-

frequency band in the opposite direction. In addition to the necessary maintenance circuits, a total of 60 two-way circuits are provided, 36 being used for transatlantic service, and the remainder being available for service between Newfoundland and the Mainland. Sixteen 2-way repeaters in rigid containers provide almost 1,000-db gain at this system's top frequency of 552 kc.

From Sydney Mines, transmission is by radio relay to the United States-Canada border and thence to Portland, Maine. This system operates at about 4,000 mc (megacycles) and includes 17 intermediate stations. From Portland, standard 12-circuit carrier- and coaxial-cable facilities are used to connect with White Plains, New York, the American switching center 30 miles north of New York City, where connection is made to the Bell System network.

The Montreal circuits leave the radio-relay route at Spruce Lake, a relay station near the border, from which point a short radio spur connects to St. John, New Brunswick, thence to Quebec on a 12-circuit open-wire carrier system and thence to Montreal on a 12-circuit cable carrier system.

Background to the Submarine Cable Systems

The submarine cable sections have been built upon a long background of experience. Some of the cable laying and design techniques go back to the early telegraph cables of almost a century ago, and Lord Kelvin's analysis of the laying process is still the standard mathematical treatise on the subject. It is also interesting to note that the firm which provided most of the cable is a subsidiary of the organization that manufactured and laid the first successful transatlantic telegraph cable some 90 years ago.

In addition to the long experience in submarine telegraphy, the transatlantic system has drawn on over a quarter of a century of experience of telephone cable work in the British Post Office and the Bell System. Experience in these two organizations has been quite different, but each in its own way has been invaluable in achieving today's system.

British Experience

In Great Britain, communication to the continent dominated the early work in submarine telephony and led to systems providing relatively large numbers of circuits over short cables laid in shallow water. Early systems were unrepeatered, but the advantages of submerged repeaters were apparent. Experimental work, started in 1938, culminated in the first submerged repeater installation in an Anglesey-Isle of Man cable in 1943. Currently, there are many repeaters in the various shallow-water cables radiating from the British Isles.

These repeaters, although of a size and mechanical structure well suited to shallow-water applications, are not structurally suited to Atlantic depths. In 1948, the Post Office began to study deep-water problems, and the first laying tests of a deep-water repeater housing were conducted in the Bay of Biscay in 1951. This housing was rigid, like the shallow-water ones, but smaller and double-ended so that the repeater was in line with the cable. Thus the rotation of the repeater, which accompanies the twisting and untwisting of the cable as tension is increased and decreased during the laying operation, could be tolerated. The housing now used by the British Post Office is basically the same as this early deep-water design, although minor modifications have been made to improve the closure and water seals.

A serious study of transatlantic telephony was begun by the Post Office in 1950 when a committee was set up to report on future possibilities of repeatered cables. As a result, it was decided, in 1952, to engineer a new telephone cable to Scandinavia, 300 nautical-miles in length, as a deep-water prototype, even though the requirements of depth, length, and channel capacity all could have been met by existing shallow-water designs.

All of the Post Office submarine systems are alike in that they use but a single cable, the go and return paths being carried by different frequency bands. The adoption of this plan was greatly influenced by the conditions under which the art developed. Because North Sea and Channel cables were highly subject to damage from fishing operations, it was desirable to limit the effects of such damage as much as possible. A single-cable system is obviously preferable under these circumstances to a system using separate go and return cables which could be put out of service by damage to either cable. Since these systems were designed for shallow-water use, the disadvantage of the additional container size required for 2-way repeaters was of no great moment compared to the advantages of a single-cable system.

UNITED STATES EXPERIENCE

In the United States, the cable art developed under very different circumstances. There was, of course, need for communication to Cuba, Catalina, Nantucket, and other off-shore locations, some of which involved conditions similar to those existing around the British Isles. The application of carrier to several of these cables occurred at an early date, but the repeater art was not directed at these shallow-water applications.

For many years, telephone communication to Europe had been an important goal and some 35 years ago a specific proposal was made by the Bell System to the Post Office for a single, continuously loaded, nonrepeatered cable to provide a single telephone circuit across the Atlantic.

This system was never built, partly because of the economic depression of the early 1930's and partly because short-wave radio was able to meet current needs. Cable studies and experiments in the laboratory and field were continued, however, and largely influenced subsequent developments. It was at this time that the physical structure of the cable now used in the transatlantic system was worked out. It was also at this time that the harmful effects of physical irregularities in the cable were demonstrated. As cables are laid in deep water, high tensions are developed which unwrap the armor wires that normally spiral about the central structure. As tension changes during the laying process, twisting and untwisting occurs which is harmless if distributed along the cable. But obstructions in the cable which prevent rotation, or any other process, such as starting and stopping of the ship which tends to localize twisting are likely to cause kinking of cable and buckling of the conductors.

By 1932, electronic technology had advanced to a point where serious consideration could be given to a wide-band system with numerous long-life repeaters laid on the bottom of the ocean and powered by current supplied over the cable from sources on shore.

The hazardous effects of obstructions in the cable demonstrated in early laying tests, indicated that the chances of a successful deep-sea cable would be greatest if the repeaters were in small-diameter flexible housings which could pass through laying gear without stopping the ship and without restricting the normal untwisting and twisting of the cable. The structure ultimately evolved, consisting of two overlapping layers of abutting steel pressure rings within a flexible waterproof container, was an important influence on the electrical design, since it placed severe limitations on size and placement of individual components.

Because these repeaters were to lie without failure for many years on the ocean bottom, it was necessary either to provide a minimum number of components of the utmost reliability, or to provide duplicate components to take over in case of failure. The size limitation favored the former approach. Similarly, the need for small size and minimum number of components militated against the use of 2-way repeaters with their associated directional filters.

Out of these considerations grew the Bell System approach to solving the transatlantic problem by the use of two cables, each with built-in flexible amplifiers containing the minimum number of components of utmost reliability and a life objective of 20 years or better.

It was not until the end of World War II that such a system could be tried. At this time, it was decided to install a pair of cables on the Key West–Havana route to evaluate the transatlantic design which had evolved in the prewar years. After further laying trials, this plan was completed in May 1950, with the laying of two cables. Each of these had three built-in repeaters lying at depths up to 950 fathoms. These cables, each about 120 nautical-miles in length, carry 24 telephone circuits. They have now been in continuous service for over 6 years without repeater failure or evidence of deterioration.

Early Transatlantic Technical Decisions

Early in 1952, negotiations concerning a transatlantic cable were again opened between the American Telephone and Telegraph Company and the British Post Office. As indicated previously, at that time each party had been laying plans for such a system. Thus it became necessary to evaluate the work on each side of the Atlantic to evolve the best technical solution.

To do this, a technical team from the Post Office visited the Bell Telephone Laboratories, in the Fall of 1952, to examine developments in the United States. The work of the preceding 30 years was reviewed in detail with particular emphasis on the development and manufacture of the 1950 Key West–Havana cables. This was followed by

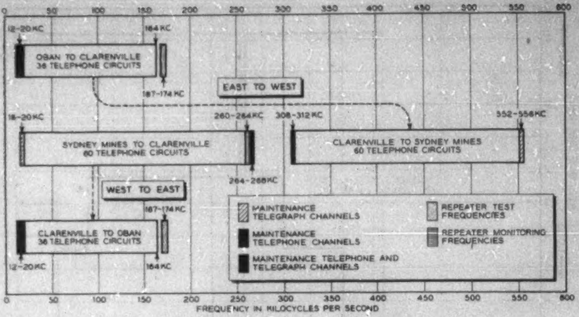

Fig. 4. Frequency allocations in submarine cable links

a visit to the Post Office by a Bell Laboratories' team to review similar work in Great Britain. Again the review was comprehensive, covering shallow-water systems as well as plans for deep-water repeaters. Each visit was characterized by a frankness and complete openness of discussion that is perhaps unusual in international negotiations.

As is apparent from the previous discussion, it was found that the basic features of a deep-water design had been completed by the Bell System. Not only had many of the components been under laboratory test for many years, but a complete system had been operating for $2^1/_2$ years between Havana and Key West. To use a phrase coined at the time, the design had proven integrity.

Because of the years of proof and the conservative approach adopted to assure long life, the design was far from modern. The electron tubes, for example, had characteristics typical of tubes of the late 1930's, when, in fact, they were designed. Similarly, other components were essentially of prewar design.

The Post Office, on the other hand, had pioneered shallow-water repeaters and were pre-eminent in this field. Their deep-water designs were still evolving and had not yet been subjected to the same rigorous tests as the Bell System repeaters. This later evolution, however, made possible a much more modern design. The electron tubes, for example, had a mutual conductance of 6,000 micromhos as compared with about 1,000 in the Bell System repeater, and thus had a potentiality for much greater repeater bandwidths.

It was apparent from these reviews that only the American design was far enough advanced to assure service at an early date. It also appeared to have the integrity so essential to such a pioneering and costly effort as a transatlantic cable. On the other hand, the more modern Post Office design had many elements of potential value. If deep-water laying hazards could be overcome and proof of reliability established, it gave promise of greater flexibility and economy for future systems.

It was on these grounds that Dr. Mervin Kelly, for the Bell System, and Sir Gordon Radley, for the Post Office, jointly recommended that the Bell System design be used for the long length and great depths of the Atlantic crossing, and the Post Office design be used for the Newfoundland–Nova Scotia link where the shallower water afforded less hazard and better observation of this potentially interesting design. The decision to use the Post Office design was subject to technical review after deep-sea laying tests and further experience with circuits and components. This review, made in June 1954, confirmed the soundness of the original recommendation.

System Planning

Planning of the individual systems began as soon as the technical decision just mentioned had been reached. By the time administrative agreements had been reached and the contract signed on Nov. 27, 1953, both parties were ready to set up system objectives and an over-all system plan. This work, too, was accomplished by a series of technical meetings held alternately in the United States and the United Kingdom, with additional meetings in Canada.

At the first of these meetings, a decision of far-reaching importance was made. It was agreed that each technical problem would be solved as it arose in so far as possible on the best engineering basis, putting aside all considerations of national pride. Adherence to this principle did much to forward the technical negotiations.

The initial joint meeting was also responsible for establishing most of the basic performance objectives of the system. The target date for opening of service, Dec. 1, 1956, had been settled even earlier and was, in the event, bettered by nearly 10 weeks.

SERVICE OBJECTIVES

A statement of the manner in which the system would be used and the services to be provided was a necessary preliminary to establishing performance objectives.

It was agreed that the system should be designed as a connecting link between the North American and European long-distance networks. As such, it should be capable of connecting any telephone in North America, ordinarily reached through the Bell System or Canadian long-distance networks, with any telephone in the British Isles or with any telephone normally reached from the British Isles through the European continental network. The system would be designed primarily for message telephone service, but consideration would be given to the provision of other services such as VF carrier telegraph, program (music), and telephotograph, as permitted by technical and contractual considerations. It was also agreed that the two submarine cable links should be so planned that it would be possible to utilize the full bandwidth in any desired manner in the future. Thus, for example, repeater test signals should be outside the main transmission band.

All elements in the submarine cable systems were to be planned for reliable service over a period of at least 20 years.

TRANSMISSION OBJECTIVES

The term objective was used advisedly in describing the aims of the system. It was agreed that such objectives were not

Table II. RMS Noise Objectives in Busy Hour

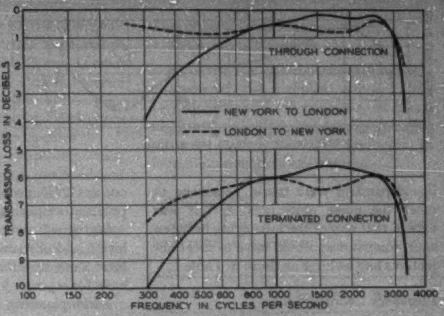

Fig. 6. Frequency characteristics of typical telephone circuit, in the two transmission directions

ironclad requirements but rather desirable goals which it was believed practical to attain with the facilities proposed. Reasonable departure from these goals, however, would not be reason for major redesign.

Since the transatlantic circuits were to connect two extensive networks, the broad objective was to add as little loss and other forms of impairment as practical. To this end, they were to be designed essentially to the standards of international circuits as defined by the CCIF (International Consultative Committee on Telephony)* and of circuits connecting main switching points in national networks, as for example, Regional Centers in the Bell System network and Zone Centers in the Post Office network.

The possibility of increasing the circuit capacity of the system by using channel spacings less than 4 kc was obvious. It was decided, however, to adopt, initially at least, the 4-kc spacing commonly used by long-distance systems on both sides of the Atlantic. This would make possible the use of standard multiplexing arrangements, and it was believed that the number of circuits provided would be adequate for the first few years of operation. It would undoubtedly be desirable to increase the number of circuits in later years, but a decision on the method to be used was left until completion of exploratory work on several methods which promised capacity increases with less degradation than narrow-band operation.

The decision to use standard terminal equipment led naturally to acceptance of the principle that the 36 circuits across the Atlantic would be assembled as three 12-channel groups in the range 60 to 108 kc, and the 60 circuits between Newfoundland and Nova Scotia as five 12-channel groups and thence as a supergroup in the range 312 to 552 kc. These are standard modulation stages in the multiplexing arrangements for broadband carrier system on both sides of the Atlantic. Two of the 12-channel transatlantic groups would be connected to New York, and the third would be split to provide $6^{1}/_{2}$ circuits to Montreal and $5^{1}/_{2}$ to New York, in accordance with the agreement.

To provide for program circuits, three eastbound and three westbound channels in each of the three transatlantic groups would be made available when required. Equipment would be provided to replace either two or three 4-kc message telephone channels by a music channel. In order to avoid the agreed group pilot frequencies and to provide service to Montreal, it was agreed to utilize the frequency bands 68 to 76 kc and 64 to 76 kc in the 12-channel groups for this purpose. Terminals of British Post Office design would be used at all points for translation between program and carrier frequencies. The normal Bell System terminals could not be used since they occupy the frequency ranges 80 to 88 kc and 76 to 88 kc which are not compatible with the split group arrangement or with the 84.08-kc end-to-end pilot.

Net Loss

The nominal 1,000-cycle net loss objective between London and New York for calls switched to other long-distance trunks at each end, i.e., the via net loss, was set at 0.5 db. For calls terminating at either New York or London, the loss would be increased by switching a 3.5-db pad in London, as recommended by the CCIF, and a 2-db pad at New York, as standard in the Bell System. Thus a New York to London call would have a net loss of 6 db.

Variations from these nominal net losses owing to temperature effects, lack of perfect equalization and regulation, etc., are to be expected, and a standard deviation of 1.5 db was set as the objective for such variations in the absence of trouble. The allocation of this variation to the various links is shown in Table I.

It is interesting to note that a smaller variation was allocated to the submarine links than to the overland links. It was believed that the more stable environment on the ocean floor would make it possible to meet the rather small variation assigned to these links.

While these loss variations are consistent with normal long-distance trunk objectives, they would not be satisfactory

---

* The CCIF bases its recommendations on a circuit 2,500 km (kilometer) (1,600 miles) in length, with implied pro rata increases for noise impairment.

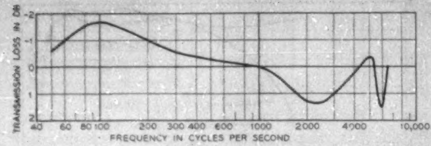

Fig. 7. Frequency characteristics of typical London–New York program channel

if compandors were found necessary to meet the noise objectives, and it was agreed that any of the links lying between such compandors would have to meet objectives half as large as those in Table I.

Frequency Characteristics

For telephone-message circuits, the frequency characteristic recommended by the CCIF, Fig. 3, was adopted with the expectation that it could be bettered by a factor of two, since channel equipments would be included at the circuit terminals only, as described later.

No specific objectives were agreed upon for the frequency characteristics of the 12-channel groups as such, but there was an expectation that ±2 db could be achieved, except for frequencies adjacent to the filters in the split group.

For program channels, the CCIF recommendations were also adopted in respect of the 2-band, 6.4 kc, and 3-band, 10 kc, arrangements. To meet the requirements of these channels and of telegraphy, an over-all frequency-stability objective of ±2 cycles was adopted.

Noise and Crosstalk

Noise objectives were established to be reasonably consistent both with Bell System and CCIF objectives for circuits of transatlantic length. The methods specified by them for the assessment of circuit noise differ in three respects; the units employed, the frequency-weighting employed, and the fraction of the busy hour for which the specified noise may occur. The meters concerned are the Bell System *2B* noise-meter (F1A weighting network) reading in dba (decibels adjusted) and the CCIF psophometer (1951 weighting network) reading in millivolts across 600 ohms. The relationship between readings on the two meters is discussed in a later paper and it will suffice here to note that, for white noise dbm (decibels referred to one milliwatt) (CCIF) = dba (Bell) − 84.

The objective for the rms circuit noise at a zero level point in the busy hour was agreed as 38 dba, i.e., −46 dbm or 3.9 mv. This was allocated between the various links as in Table II.

For the program channels, the agreed noise objective was −50 dbm as measured on a CCIF psophometer with a 1951 program-weighting network.

Statistical data on probable speech levels and distributions at London and New York terminals were provided as a basis for repeater loading studies.

Early planning studies indicated that these objectives would probably be met on all, or nearly all channels without resort to compandors. If, as the system aged, the noise increased owing to increasing misalignment, the use of compandors would offer a means of reducing message circuit noise below the objectives.

The minimum equal-level crosstalk loss between any two telephone channels was set at 56 db for any source of potentially intelligible crosstalk. For channels used for VF telegraph, the equal-level crosstalk loss between go and return directions was set as a minimum of 40 db. For all program channels, the minimum crosstalk attenuation would be 55 db.

Restrictions of Telegraph and Other Services

Since the system was being designed primarily for message telephone service, it was agreed that a channel used for any other service should not contribute more to the system rms or peak load than if this channel were used for message telephone, except by prior agreement between the engineering representatives of the Post Office, Bell System, and Canadian Overseas Telecommunication Corporation.

SIGNALING OBJECTIVES

In order to conserve frequency space, it was decided to transmit all calling and supervisory signals within the telephone channel bands. To avoid transmission degradation, it was agreed that the signaling power and duration would not amount to more than 9 milliwatt-seconds in the busy hour at a zero level point. This would not contribute unduly to the loading of the system.

It was agreed that, for initial operation, ringdown signaling would be employed, but the system design should be such as to permit the use of dialing at a later date.

ECHO SUPPRESSORS

Echo control was considered essential, since the via net loss of the transatlantic circuits would be only 0.5 db, with a one-way transmission time of 35 milliseconds. Echo suppressors would be provided initially at New York and Montreal only, and arrangements would be made in London to cut out such suppressors as may be fitted there on continental circuits, when these are used for extension of the transatlantic circuits. It was recognized, however, that other suppressors might be encountered in the more remote parts of continental and United States extensions. The general problem of how best to arrange and operate echo suppressors on very long switched connections is one which remains for consideration later.

MAINTENANCE AND OPERATING SERVICES

Telephone Speaker and Telegraph Printer Circuits

The need for telephone and telegraph circuits for maintenance and administration was recognized, and it was agreed to provide the following circuits, shown in Fig. 4, on the submarine links at frequencies immediately outside the main transmission bands, where inferior and somewhat uncertain characteristics might be expected: 1. A 4-kc band, possibly substandard in regard to noise, equipped with band-splitting equipment (EB Banks) to provide two half-bandwidth telephone (speaker) circuits, 2. Two frequency-modulated telegraph (printer) circuits. These circuits would be extended over the land circuits to the terminal stations by standard arrangements as needed, and would be used to provide the following facilities:

1. An omnibus speaker circuit connecting the principal stations on the route, including Montreal.
2. A speaker circuit for point-to-point communication between the principal stations, i.e., noncontinuous.
3. A direct printer circuit between London and White Plains.
4. An omnibus printer circuit as 1.

Repeater Test Frequencies

In each submarine cable link, test frequency bands were required for monitoring repeater performance. These are indicated in Fig. 4.

Pilot Frequencies

It was agreed to provide pilot facilities throughout the route for line-up maintenance and regulation purposes. In addition to the usual pilots on the inland networks, there would be provided:

1. A 92-kc pilot in each 12-channel group, continuous only in a particular section of the route and fitted with a recording voltmeter at the receiving end of that section.

Vol.
Pt. 1
1956

2. An 84.08-kc over-all pilot in each 12-channel group as recommended by the CCIF. This would transmit continuously over the entire route and would be monitored and recorded at every main station.

CONNECTIONS BETWEEN COMPONENT LINKS

At the time that the objectives were being established, a far-reaching decision was made to employ channel equipment at London, New York, and Montreal only, and to adopt the frequency band 60 to 108 kc as the standard frequency for connecting the various parts of the over-all system. By adopting this band as standard for the transatlantic system, it also became possible to interconnect readily with land systems at each end.

This agreement also facilitated decisions on responsibility for design and manufacture of equipment. For example, it became logical to define each submarine system as the equipment between points where the 60- to 108-kc band appeared, i.e., the group connecting frames. Thus, these systems would include not only the cable, repeaters, and power supplies, but also the terminal gear to translate between 60 to 108 kc and line frequency of the submarine system. It also became logical to assign responsibility for the manufacture of all of this equipment to the administration responsible for the specific system design, i.e., responsibility for the Oban-Clarenville link to the Bell System and the Clarenville–Sydney Mines link to the Post Office.

The Realization of the System

With decisions reached on the system objectives and interconnecting arrangements, it became possible to lay out jointly a detailed over-all plan and for each administration to proceed with developing and engineering the links under its jurisdiction.

There was an understanding that there should be no deliberate attempt to make the characteristics of one link compensate for those of another, and so it would be incumbent on the administrations to produce the best possible group characteristic on each link.

The over-all plan for the system, as finally developed, is shown in Fig. 2. Except for the necessity to split one of the three transatlantic groups in each direction to provide 6½ circuits to Montreal and 5½ to New York, which required specially designed crystal filters, no unusual circuit facilities were required.

Special equipment arrangements were called for at Sydney Mines and Clarenville to provide security for the Montreal-London circuits where they appeared in the same office with White Plains–London circuits. In these cases, a special locked room was constructed to house the equipment associated with the channel group containing the Canadian circuits.

The details of how the two all-important submarine cable links were designed and engineered to meet their individual objectives are given in companion papers. The efficiency and integrity of these two links are the highest that could be devised by engineers on both sides of the Atlantic.

Finally, each section of the connecting links was lined up and tested individually before bringing them all together as an integrated system.

Over-all Performance of the System

The system went into service on Sept. 25, 1956, so soon after completion of some of the links that it was not possible to include all the final equalizers. Nevertheless, after completion of the initial over-all line-up, the performance has been found to meet very closely the original objectives. The system went into service without the use of compandors on any of the telephone circuits, but compandors are included in the program equipment. At the time of this writing, only the 2-channel program equipment is available for use.

FREQUENCY CHARACTERISTICS OF 12-CHANNEL GROUPS

Fig. 5 shows the frequency characteristic of one of the 12-channel groups, link by link and over-all, measured at group frequencies corresponding to 1,000 cycles on each channel. In both of the complete London-New York groups, the deviation from flat transmission is within ±1.5 db, and some further improvement is to be expected when the equalization is finalized. For the split group, the characteristics are similar except for the effect of the splitting filters.

VARIATION OF OVER-ALL TRANSMISSION LOSS

The system has, of course, only been completed for a short time, but the indications so far are that the standard deviation of the transmission loss, as indicated by the 84.08-kc group pilots is well within the objective of 1.5 db. Alarms operate when the received pilot level deviates by ±4 db and, so far, these alarms have not operated under working conditions.

FREQUENCY CHARACTERISTICS OF TELEPHONE CIRCUITS

Fig. 6 shows the measured frequency characteristic of a typical circuit in the two directions of transmission, as measured in the through and terminated conditions. Half of the CCIF limits are, in fact, met on most of the circuits.

CIRCUIT NOISE

The circuit noise, referred to a zero level point, is as follows:

Link	Best, Dba	Worst, Dba
London–New York	30	36
New York–London	29	41
London–Montreal	30	33
Montreal–London	30	31

Two circuits at present exceed the objective of 38 dba in the New York-London direction only; the higher noise levels refer to the high-frequency channels in the Oban-Clarenville cable. After additional data on the effect of cable temperature variations are accumulated, refinements will be made in the equalization and adjustment of levels on the Oban-Clarenville link. It is expected that the two worst channels can then be made to meet the objectives, still without the use of compandors.

FREQUENCY CHARACTERISTICS OF PROGRAM CHANNELS

Fig. 7 shows the measured frequency characteristic of a London-New York program channel. This is typical.

LONDON-MONTREAL TELEGRAPH CHANNELS

In the agreement, it was envisaged that at least six 50-baud telegraph channels could be provided in each direction in the Canadian half circuit. In fact, 11 such channels have been provided using carriers spaced at 120 cycles and frequency modulation. The telegraph distortion due to the cable system with start-stop signals is about 4 per cent in every case, thus making the circuits suitable for switched connections, without regeneration, up to the same limits as inland systems.

Tests over the system indicate that the channel speed can be raised satisfactorily to 80 bauds on at least ten of the channels. By the adoption of synchronous working, it appears that time-division multiplex systems can be operated on these ten channels to double their capacity at a later date.

Conclusions

The transatlantic cable system has presented unique problems in system planning and design. It has been necessary to design the system to connect the facilities of many countries and to provide for cable communication of unprecedented length. But the stringent design objectives necessary to meet these requirements have not been the only challenge to the designer. It has been necessary to meet these objectives with a system which for over 2,000 miles of its length could not be altered to the slightest extent once it had been placed on the ocean bottom. Except for the adjustments which can be made at the shore terminals of the submarine links, it has not been permissible to make any of the multitude of small design changes, substitutions, and adaptations which are so commonly required in new systems to achieve the design objectives.

The success achieved in meeting the original objectives is a measure of the realism of the early planning as well as the diligence with which the project was carried forward to completion. The accomplishment of getting into commercial service a working system with many complex links 6 weeks after the final splice was dropped overboard, and nearly 10 weeks ahead of schedule, is a further tribute to the close co-operation of the technical people of three nations.

System Design for the North Atlantic Link

H. A. LEWIS R. S. TUCKER G. H. LOVELL J. M. FRASER

Synopsis: Specific aspects of the transatlantic cable system are covered in companion papers. The purpose here is to examine the design and performance of the North Atlantic link, including consideration of factors governing the choice of features, a description of the operational design of the facility, and an outline of those measures available for future application in the event that faults or aging require corrective action.

Description of Link

THAT PORTION of the transatlantic system[1] which connects Newfoundland and Scotland consists of a physical 4-wire, repeatered, undersea link of Bell Laboratories design, with appropriate terminal and power feeding equipment in cable stations at Clarenville and at Oban.

The various elements comprising the link are shown in block form in Fig. 1. The termination points at each end of the link are the group distributing frames (GDF), where the working channels are brought down in three groups to the nominal group frequency band, 60 to 108 kc. At the west end, this point provides the interconnection between the North Atlantic and the Newfoundland–Nova Scotia links. At the east end it is the common point between the North Atlantic link and the standard British long-distance plant over which the circuits are extended to London.

Two separate coaxial cables connect Clarenville with Oban, one handling east-to-west transmission, the other west-to-east. Each is about 1,940 nautical miles long. A total of 102 repeaters are installed in the two cables, at nominal intervals of 37.5 nautical miles. The cables also contain a number of simple undersea equalizers which are needed to bring system performance within the specified objectives.

The working spectrum of each cable extends from 20 to 164 kc, providing for thirty-six 4-kc message channels. Below this band are assigned the telephone (speaker) and telegraph (printer) circuits needed for maintenance and administration of the facility. Above the working band, between 167 and 174 kc, are the crystal frequencies which permit evaluation of the performance of each repeater individually from the shore stations.

The signal complex carried by the cables is derived in the carrier terminals from the signals on the individual voice frequency circuits by conventional frequency division techniques such as are employed in the Ball types *J*, *K* and *L* broad-band carrier systems manufactured by the western Electric Company; see Fig. 2. These signals are applied to the cable through a transmitting amplifier which provides necessary gain and protects the undersea repeaters against harmful overloads. At the incoming end of each cable, a receiving amplifier provides gain and permits level adjustment.

Shore equalizers, next to the transmitting and receiving amplifiers, insert fixed shapes for cable length and level compensation. Adjustable units provide for equalization of the system against seasonal temperature changes on the ocean bed, and some aging.

The power equipment[2] at each cable station includes: 1. regular primary power with Diesel stand-by, 2. rotary machines for driving the cable current supplies, with battery stand-by, 3. battery plants for supplying the carrier terminal bays, and 4. last, but by no means least in complexity, the cable current supplies. These latter furnish regulated direct current to a series loop consisting of the central conductors of the two cables, with their repeaters. A power system ground is provided at the mid-point of the cable current supply at each cable station.

Factors Affecting System Design

General

A repeatered submarine cable system differs from the land-wire type of carrier system in two major respects. First, the cost of repairing a fault, and of the concurrent out-of-service time, is so great as to put an enormous premium on integrity of all the elements in the system and on proper safeguards in the system against shore-end induced faults. Second, once such a system is resting on the sea bottom, it is accessible for adjustment only at its ends. These two restrictions naturally had a profound influence on the design of the North Atlantic link.

Proved Integrity

Assurance of reliability dictated use of elements whose integrity had actually been proved by successful prior experience in the laboratory or in the Bell System. This resulted in adoption of a coaxial cable structure explored by the Laboratories soon after the war, field tested in the Bahamas area in 1948, and applied commercially on the USAF Missile Test Range project[3] in 1953. It also resulted

Fig. 1. Schematic, North Atlantic link

in specification of a basic flexible repeater design which had been under test in the Laboratories since before the war, and had been in use on the Key West–Havana submarine cable telephone system since 1950.[4]

The cable adopted was the largest that had actually been successfully laid in deep water, and its size afforded an important benefit in the form of reduced unit attenuation. The structure and characteristics of this cable are covered in detail in a companion paper.[5] Suffice it to point out here that by its adoption for the North Atlantic link, there were specified for the system designers: 1. the attenuation characteristic of the transmission medium, 2. the influence on this of the pressure and temperature environments, 3. the unit contribution of the cable to the resistance of the power loop, and 4. the impedances faced by the repeaters.

The adaptation[6] of the basic Key West–Havana repeater design to the present project likewise presented the system designers with certain restrictions. Most important, the space and form of the long, tubular structure limited the size of the high-voltage capacitors in the power separation filters, and thus their voltage rating, to the extent that this determined the maximum permissible number of repeaters. Likewise the performance of the repeater circuit was at least partially defined because of several factors. One was the effect of the physical shape on parasitic capacitances in the circuit, which in turn reacted on the feedback and hence on modulation performance, gain-bandwidth, and the aging characteristic. Use of the Key West–Havana electron tube influenced these factors and also tended to fix the input noise figure and load capacity.

In similar respects, the principle of proved integrity reacted into the broad consideration of system design. For instance, in a long system having many repeaters in tandem, automatic gain control (gain regulation) in the repeaters provides an ideal method for minimizing the amount of the total system margin which must be allocated to environmental loss variations. However, this would have required adoption of elements of unproved integrity which might have increased the probability of system failure. So the more simple and reliable alternative was adopted, i.e., fixed gain repeaters with built-in system margins.

System Inaccessibility

The inaccessibility of the undersea system for periodic or seasonal adjustment and the decision to avoid automatic gain regulation were major factors in the allocation of system margins between undersea and shore locations. To avoid wasting such a valuable commodity as margin required the most careful consideration of means of trimming the system during laying. Equalization for control of misalignment in the undersea link is a function of the match between cable attenuation and repeater gain. Generally speaking, these are fixed at the factory. Very small unit deviations from gain and loss objectives could well add to an impressive total in a 3,200-db (decibel) system. Accordingly, it was necessary to plan for periodic adjustment of cable length during laying, and where necessary, insertion of simple mop-up undersea equalizers at the adjustment points.

Design of High-Frequency Line

Terminology

The high-frequency line, as the term is used here, includes the cable, the undersea repeaters, the undersea equalizers, and the shore-station power separation filters, transmitting and line-frequency receiving amplifiers, and associated equalizers.

Repeater Spacing and System Bandwidth

As in most transmission media, the attenuation of the cable increases with increasing frequency. Hence the greater the bandwidth of the system, the greater the number of repeaters needed.

In this system, powered only from its ends, the maximum permissible number of repeaters, and thus the repeater spacing, is determined by a direct voltage limitation, as explained later.

With the repeater spacing fixed, and the type of cable fixed, the required repeater gain versus frequency is known to the degree of accuracy that the cable attenuation is known. The frequency band that can be utilized, then, depends on repeater design considerations, including gain-bandwidth limitations, signal power capacity, and signal-to-noise requirements.

The early studies of the transatlantic system were based on "scaling up" the Havana–Key West system.[4] In these studies consideration was given to extending the band upward as far as possible by using compandors[7] on the top channels, thus lightening the signal-to-noise requirements on these channels by some 15 db, provided they are restricted to message telephone service.

Fig. 2. Block schematic of terminals, North Atlantic link

As the repeater design was worked out in detail, however, it became evident that a rather sharp upper frequency limit existed. This resulted from the parasitic capacitances imposed by the size and shape of the flexible repeater, the degree of precision required in matching repeater gain to cable loss in such a long system, and the feedback requirements as related to the requirement of at least 20 years' life.

These limitations resulted in the decision to develop a system with 36 channels of 4-kc carrier spacing, utilizing the frequency band from 20 to 164 kc per second.

SIGNAL-TO-NOISE DESIGN

Scaling-up of Key West–Havana System

The length of the North Atlantic link was to be about 16 times that of the Havana–Key West system. The number of channels was to be increased as much as practicable. The length increase entailed an increased power voltage to ground on the end repeaters. Increase in length and in number of channels entailed increased precision in control of variations in cable and repeaters. Work on these and other aspects was carried on concurrently, to determine the basic parameters of the extended system.

Increasing cable size decreases both the attenuation and the d-c resistance and, in turn, the voltage to ground on the end repeaters. It was soon decided that the largest cable size that could be safely adopted was the one used in the Bahamas tests. This has a center-conductor sea-bottom resistance of about 2.38 ohms per nautical mile. It consumes about 28% (per cent) of the total potential drop in cable plus repeaters.

Number of Repeaters

As indicated earlier, the factor which emerged as controlling the number of repeaters was the direct voltage to ground on the end repeaters. Considerations which entered into this were: voltage which blocking capacitors could safely withstand over a life of at least 20 years; voltage which other repeater elements such as connecting tapes between compartments could safely hold without danger of breakdown or corona noise; initial power potential and possible need for increasing direct cable current later in life to combat repeater aging; allowance for repair repeaters; and a reasonable allowance for increased power potential to offset adverse earth potential. Let

R = d-c resistance of center conductor, ohms per nautical mile
L = length of one cable in nautical miles (the length of a cable is greater than the length of the route because of the need to pay out slack. The slack allowance, which averages 5% in deep water on this route, helps to assure that the cable follows the contour of the bottom)
E_{rep} = voltage drop across one repeater at current I
I = ultimate (maximum) line current, amperes
N = ultimate number of submerged repeaters, in terms of equivalent regular repeaters
n = allowance for repair repeaters, in terms of number of regular submerged repeaters using up same voltage drop
E_m = maximum voltage to ground at shore-end repeaters at end of life, and in absence of earth potential
S = spacing of working regular repeaters, nautical miles

Then, for the ultimate condition

$$2E_m = LIR - 2SIR + NE_{\text{rep}} \quad (1)$$

in which the term $2SIR$ accounts for the sum of the cable voltage drops on the two shore-end cable sections; the sum of their lengths is assumed, for simplicity, to equal $2S$. This equation also neglects a small allowance (less than 0.6 volt per mile) for the voltage drop in cable added to the system during repair operations. Also

$$S(N - n + 1) = L \quad (2)$$

because the repeater spacing is determined by the number of working regular repeaters. From equations 1 and 2

$$2E_m = LIR + NE_{\text{rep}} - 2LIR/(N - n + 1) \quad (3)$$

Vol, Pt. 1 195

Table I.

Channel, Frequency	N_{in} = Approximate Input Noise, Dba	G = Approximate Repeater Gain, Db	TL = Approximate Output Trans Level, Db	N_r = Resulting Noise, Dba
Top	−55.5	60.7	− 6	28.4+d_r
Middle	−53	45	−11	20.2+d_r
Bottom	−46	22	−19	12.2+d_r

The allowance *n* for repair repeaters was determined after studies of cable fault records of transoceanic telegraph cables, including average number of faults per year and proportion of faults occurring in shallow water. If the fault occurs in shallow water, as is true in most cases (because of trawler activity, ship anchors, and icebergs) the net length of cable added to the system and the resulting attenuation increase are small. Several shallow-water faults might be permissible without adding a repair repeater. Therefore it was decided to let $n=3$. Since the repair repeater is a 2-tube repeater, while the regular repeater has 3 electron tubes, $n=3$ corresponds to about five repair repeaters per cable.

To determine the maximum voltage E_m, it was necessary to consider blocking capacitors and earth potentials. Based on laboratory life tests, the blocking capacitor developed has an estimated minimum life of 36 years at 2,000 volts. It is estimated that life varies inversely as about the fourth power of the voltage. The potential actually appearing on these capacitors is determined by the distance of the repeater from shore, the power potential applied to the system, and the magnitude and polarity of any earth potential.

Earth potential records on several Western Union submarine telegraph cables were examined. These covered a continuous period from 1938 to 1947, including the very severe magnetic storms of April 1938, and March 1940. It was judged reasonable to allow a margin of 400 volts (200 volts at each shore station) for magnetic storms during the final years of life of the system.

Table II.

Channel, Frequency	M = Estimated Misalignment, Db	d_r = Resulting Noise Increase, Db	N_s = Resulting System Random Noise, Approximate, Dba
Top	12	7.4	36
Middle	10	6.0	26
Bottom	6	3.4	16

With an assumed maximum voltage of 2,300 volts on the end repeaters due to cable-current supply equipment, and 200 volts per end as allowance for the maximum opposing earth potential which the system would be permitted to offset without automatic reduction of the cable current, the voltage across the end repeater in late years of life (i.e., after line current had been increased to offset aging) would normally be 2,300 and would infrequently rise to 2,500. On the rare occasions where earth potential would rise above twice 200 volts, the cable current would be somewhat reduced and the transmission affected to a reasonably small extent. In the early years of life, when the cable-current supply voltage would normally be about 2,000 volts, an opposing earth potential of twice 500 volts could be accommodated without affecting cable current; according to the telegraph cable records this would practically never occur. With conditions changing in this way over the years, the life of the blocking capacitors in the end repeaters was calculated to be satisfactory. Accordingly, E_m was established as 2,300 volts.

The system length *L* was estimated as about 1,985 nautical miles and the ultimate current *I* was estimated as 0.250 ampere, with a corresponding ultimate E_{rep} of about 62.8 volts.

Substituting in equation 3

$N=55$

$N-n=52$ working repeaters

$S=37.4$ nautical miles

From a later estimate of $L=1{,}955$ nautical miles, *S* calculates to be 36.9. The repeater design was based on this spacing in the deep-sea temperature and pressure environment. Subsequently, after better knowledge had been obtained of the cable attenuation in deep water, the actual repeater spacing for the main part of the crossing was changed to about 37.4 nautical miles for the eastbound (no. 1) cable and 37.6 for the westbound. Only 51 repeaters were required in each cable.

Number of Channels

The number of channels which could be transmitted was determined by the upper and bottom boundary frequencies. In this system the bottom frequency was established at 20 kc, primarily because of the loss characteristic of the power separation filters.[6]

Table III.

Channel, Frequency	Weighted Noise in Dba at Zero Transmission Level: Second-Order Products	Third-Order Products	Total
Top	8.2	8.5	11.8
Middle	0.2	3.8	5.4
Bottom	−1.8	2.5	3.9

Preliminary studies were made to estimate the usable top frequency. For a system having a fixed number of repeaters, the frequency falls where the maximum permissible repeater gain equals the loss of a repeater section of cable, which varies approximately as the square root of frequency. The repeater gain is the difference between the repeater input and output levels. The minimum permissible transmission level at the repeater input depends on the random noise (fluctuation noise) contributed by cable and repeaters, and on the specified requirement for random noise. The maximum permissible transmission level at the repeater output may depend on the modulation noise contributed by repeaters below overload, or on overload on the peaks of the multichannel signal complex. In this system, overload was found to be the controlling factor.

An important consideration was to provide enough feedback in the repeater so that at the end of 20 years the accumulated gain change (Mu-Beta effect) in all of the repeaters would not cause the signal-to-noise performance to fall outside limits. The usable feedback voltage was scaled from the Havana–Key West design according to the relation that this voltage varies inversely as the 5/3 power of the top frequency. Electron-tube aging was estimated from laboratory life tests on the Key West–Havana types of tubes.

Concurrently, detailed theoretical and experimental studies being conducted on the transmission design of a repeater suited to transatlantic use with the chosen type of cable, as discussed in a companion paper.[7] Intimate acquaintance with the

Fig. 4 (above). Transmitting equalizers: block schematic

repeater limitations led to a decision in 1953 to develop a system with a working spectrum of 144 kc (36 channels) and a top frequency of 164 kc. Use of compandors would not appreciably increase this top frequency.

Computed Noise

When the repeater design was established, the remaining theoretical work on signal to noise consisted in refining the determination of the repeater output and input levels; computations of system noise, and comparison of this with the objectives to establish the margin available for variations; and determination of the necessary measures in manufacturing and cable laying so that these margins would not be exceeded by the deviations from ideal conditions which would occur. These deviations assumed great importance, because they tended to accumulate over the entire length of the system, and because many of them were unknown in magnitude before the system was actually laid.

The repeater levels and the resultant system noise were computed as follows: It was recognized that the output levels of different repeaters would differ somewhat at any given frequency. The maximum allowable output level of the highest-level repeater was computed by the criterion that the instantaneous voltage at its output grid should be expected to reach the load-limit voltage very infrequently. This is the system load criterion established by Holbrook and Dixon.[8] It premises that in the busy hour, the load-limit voltage (instantaneous peak value) should be reached 0.001% of the time, or less. It is probable that the level could be raised 2 db higher than the one computed in this way without noticeable effect on intermodulation noise.

An important factor in the Holbrook-Dixon method is the talker volume distribution. Because of the special nature of this long circuit, a careful study was made of the expected United States talker volumes.

First, recent measurements of volumes on long-distance circuits were examined for the relation between talker volume and circuit length. They showed a small increase for the longer-distance circuits. This relation was extrapolated by a small amount to reach the 4,000-mile value appropriate to the New York-London distance.

Second, an estimate was made of the probable trends in the Bell System plant in the next several years, which might affect the United States volumes on transatlantic cable calls.

The result of this was a "most probable US volume distribution." This distribution, which had an average value of −12.5 vu (volume units) at the zero level point, with a standard deviation of 5 db, agreed very well with one furnished by the British Post Office and based on calls between London and the European continent. A further small allowance was then made for the contribution of signaling tones and system pilots, which brought the resultant distribution to an average value of −12 vu at zero level of the system (the level of the outgoing New York or London or Montreal switchboard), and a standard deviation of 5 db. It is approximately a normal-law distribution (expressed in vu), except that the very infrequent high volumes are reduced by load limiting in the inland circuits.

The other data needed for system load computations are the number of channels, and the "circuit activity," i.e., the per cent of time during the busy hour that the circuit is actually carrying voice in a given direction (eastbound or westbound). The circuit activity value used in designing United States long-distance multichannel circuits is 25%; for the transatlantic system 30% was used.

The peak value of the computed system multichannel signal is the same as the peak value of a sine wave having an average power of +17.4 dbm (decibels referred to one milliwatt) at the zero transmission level point of the system.

This value, together with the measured sine-wave load capacity of the undersea repeater, determines the maximum permissible output transmission level of the repeater. The measured sine-wave load capacity is about +13.5 dbm at 164 kc. Hence the maximum permissible output transmission level for the 164-kc channel is $+13.5-17.4=-3.9$ db.

If the relative output levels of the various submarine repeaters were precisely known, the highest-level repeater could have an output transmission level of −3.9 db at 164 kc. An allowance of about 2 db was made for uncertainty in knowledge of repeater levels, giving −6 db as the design value for the maximum repeater output level at 164 kc. (At the time of writing, the no. 1 cable, eastbound, is set up with a somewhat lower maximum output level than this; the safe increase in level will be determined later.)

The repeater has frequency shaping in the circuit between the grid of its output tube and the cable. The maximum repeater output at lower frequencies is smaller than at 164 kc, but the maximum voltage on the output grid, from an overload standpoint, is approximately constant over the 20- to 164-kc band.

The transmission level of the maximum level repeater output is thus determined, based on load considerations. Another factor which might limit this level is modulation noise. This, however, was found to be less of a restriction than the load limitation.

With the output level determined, the random noise and the modulation noise for the system can be computed. The random-noise computation is made on the assumption that all repeaters are at the same level, and then a correction is made for the estimated differences in levels of the various repeaters. The equation is

$$N_0 = N_{in} + G - TL + 10 \log n + d_r$$

where

N_0 = system random noise, in dba (decibels adjusted), referred to zero transmission level. ("Dba" is a term used for describing the interfering effect of noise on a speech channel. Readings of the 2B noise meter with F1A weighting may be converted

IN
OUT
APPROX. LOSS IN DB AT 164 KC

Fig. 5. Transmitting temperature equalizer

to dba by adding 7 db. Dba may be translated to dbm, unweighted, by noting that flat noise having a power of 1 milliwatt over a 3,000-cycle band equals approximately +82 dba, and that 1 milliwatt of 1,000-cycle single frequency power equals +85 dba)

N_{1n} = random noise per repeater in dba, referred to repeater input level

G = repeater gain in db

TL = transmission level of repeater output

n = number of undersea repeaters

d_r = db increase in noise due to differing output levels of the various repeaters as compared to the highest-level repeater

At the top frequency of 164 kc, $TL=-6$ db as seen in the foregoing, $G=60.7$ db, and N_{1n} is about -55.5 dba, which corresponds to a noise figure of about 2 db. Hence, for 52 repeaters, $N_0=-55.5+60.7-(-6)+10\log 52+d_r=28.4+d_r$.

At lower frequencies, the noise power referred to repeater input is greater because part of the equalization loss is in the input circuit; the repeater gain is less, to match the lesser loss of a repeater section of cable; and the repeater output level is lower on account of the equalization loss from output grid to repeater output. This is shown in Table I.

To estimate d_r (which is a function of frequency) before the cable was laid, the factors were studied which might contribute to differences between the levels of the various repeaters. Estimates were made of probable total misalignment, by which is meant the level difference between highest-level and lowest-level repeaters. These values, together with estimates of the resulting noise increases, are shown in Table II. This is based on the assumption that the repeater levels would be distributed approximately uniformly between highest and lowest. The position of a repeater along the cable route is not significant.

A study was made of the expected intermodulation noise. This noise is affected by repeater level differences, by talker volumes, and by circuit activity. It has a time distribution, the most attention being given to the rms modulation noise in the busy hour.

Modulation noise was computed in two ways: by the Bennett method,[9] and by the Brockbank-Wass method.[10] Results by the two methods are in fairly good agreement. The values computed by the Bennett method are shown in Table III.

Because noise powers, not dba, are additive, these values of modulation noise would contribute only a very small amount to the total noise in the deep-sea cable system, as previously stated. The following table for adding two noises expressed in dba shows the magnitudes of the increases.

Db difference between larger and smaller noises	2	4	6	8	10	15	20
Resulting db to be added to larger noise to get sum of the two	2.1	1.4	1.0	0.6	0.4	0.1	0+

Other possible contributory sources of noise in the deep-sea cable system are noise in the terminals, noise picked up in the shore lead-in cables, and corona noise in the repeaters. The system has been designed so that the expected total of these is small. Hence the estimate of total deep-sea cable system noise, made before cable laying, gave the values shown in Table IV, to the nearest decibel.

MISALIGNMENT CONTROL

Objective

Since the noise objective for the deep-sea cable link was set as 36 dba in the joint meetings of the British Post Office and Bell System representatives, the foregoing estimate of system noise led in turn to the objective that the system be manufactured and laid in such a way that the misalignment, including effects of seasonal temperature change, should be no greater in the top channel than the value assumed in the estimate, which was 12 db. Half of this was allotted to initial misalignment and half to effects of temperature change. Greater misalignments were permissible at lower frequencies. Control of this misalignment required extensive consideration in the equalization design of the system.

Causes of Misalignment

The basic causes of misalignment can be grouped as follows: those producing unequal repeater levels when the system is first laid; those resulting from changes in cable loss produced by changes in sea-bottom temperature; and those from aging of the cable or repeaters.

There are a large number of possible causes of initial misalignment. While the cable and repeaters were manufactured within very close tolerances to their design objectives, they could not exactly meet those objectives. In addition, the cable loss as determined in the factory must be translated to the estimated loss on sea bottom, and the length of each repeater section must be tailored in the factory so that its expected sea-bottom loss will best match the repeater gain. Possible sources of error in this process include: uncertainty in temperature of the cable when it is measured in the factory, and in its temperature on the sea bottom; uncertainty in temperature and pressure coefficients of attenuation; changes in cable loss between factory and sea-bottom conditions, not accounted for by pressures and temperature coefficients.

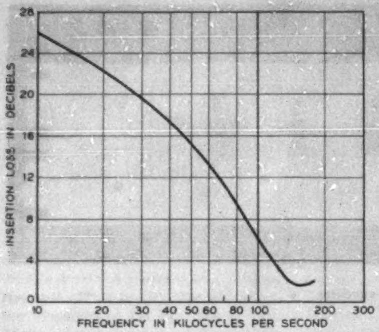

Fig. 6. Transmitting equalizer loss-frequency characteristic

These latter changes in cable loss were called "laying effect." The determination of the magnitude of laying effect, and its causes, are discussed in the paper on cable design.[5] Suffice it to say here that after measuring the loss of a length of cable in the factory and computing the sea-bottom loss, the computed result was a little greater than the actual sea-bottom loss. The difference, i.e., the laying effect, was approximately proportional to frequency, and was greater for deep-sea than for shallow-water conditions. Its existence was confirmed by precise measurements on trial lengths of cable, taken early in 1955 in connection with cable-laying tests made near Gibraltar.

Laying effect had been suspected from statistical analysis of less precise tests of repeater sections of cable generally similar to transatlantic cable, as measured in the factory and as laid in the vicinity of the Bahamas. However, the repeater design had of necessity been established before the Gibraltar test results were known. The consequence was a small systematic excess of repeater gain over computed cable loss, approximately proportional to frequency, and amounting at the top frequency to about 0.04 db per nautical mile, on the average, for deep-sea conditions, and about 0.025 db per mile for shallow-water conditions. While this difference appears small, it would accumulate in a transatlantic crossing of some 1,600 miles of deep sea and 350 miles of relatively shallow sea, to about 75 db at the top frequency. This would be enough to render almost half of the channels useless if no remedial action were taken.

After a system is laid, changes in cable loss or repeater gain may occur. These may be caused by temperature effects and by aging of cable or repeaters.

Comprehensive studies of the expected amounts of temperature change were made both before and after the 1955 laying. (Factual data on deep sea-bottom temperatures are elusive. Many of the existing data were acquired by unknown methods under unspecified circumstances, with apparatus of unstated accuracies. Statistical analysis of selected portions of the data leads to the quoted estimates.) These gave an estimate of 0 to ±1 F (degrees Fahrenheit) annual variation in sea-bottom temperature in the deep-sea part of the route (about 1,600 nautical miles) and perhaps ±5 F on the continental shelves (about 350 nautical miles). Use of these figures leads to a ±5d-b variation in system net loss at 164 kc from annual temperature changes. If the deep-sea bottom temperature did not change at all, the estimated net loss variation due to temperature would be about half of this.

Control of Misalignment

In the control of misalignment, the first line of defense against variations leading to this condition is the design and production of complementary repeaters and cable. This is discussed in companion papers.

Signal-to-noise changes from undersea temperature variations were minimized by providing adjustable temperature equalizers at both the transmitting and the receiving terminals, and devising a suitable method of choosing when and how to adjust them.

Partial compensation for laying effect was carried out at the cable factory by slightly lengthening the individual repeater sections. In the 1955 cable, where the factory compensation was based on early data, the increased loss compensated for about two fifths of the Gibraltar laying effect at the top frequency. For the 1956 cable, the 1955 transatlantic experience was benefited by, and the compensation was increased to nearly twice this amount. Since the loss of the added cable is approximately proportional to the square root of frequency and the laying effect is approximately directly proportional to frequency, the proportion of laying effect compensated varied with frequency, and a residual remained which had a loss deficiency rising sharply in the upper part of the transmitted band.

The remainder of the laying effect which was not compensated for in the factory, as well as other initial variations, were largely compensated by measures taken during cable laying at intervals of 150 to 200 miles. The whole length of the cable was divided into eleven "ocean blocks," each either four or five repeater sections long. At each junction between successive ocean blocks, means were provided to compensate approximately for the excess gain or loss which had accumulated up to that point.

These means were twofold. The first means was adjustment of the length of the repeater section containing the junction. For this purpose, the beginning of each block, except the first, was manufactured with a small excess length of cable. This was to be cut to the desired length as determined by shipboard transmission measurements.

The second means was a set of undersea equalizers. These equalizers were fixed series networks, encased in housings similar to the repeater housings but shorter.

Before the nature of the laying effect was known, it had been planned to have equalizers with perhaps several shapes of loss versus frequency; but to combat laying effect, nearly all were finally made with a loss curve sloping sharply upward at the higher frequencies, as shown in Fig. 3. (This characteristic was based on a statistical analysis of the data on similar cable laid for the Air Force project.) Because the equalizer components had to be manufactured many months in advance and then sealed into the housings, last-minute designs of undersea equalizers were not practical. The proven-integrity principle prevented use of adjustable units. Because the equalizers were series-type, each block junction has located at approximately mid-repeater section to minimize the effects of reflections between equalizer and cable impedances.

The actual adjustments at block junctions were determined by a series of transmission measurements during laying, as described in the companion paper on cable laying.[11] Six equalizers were used at block junctions in the 1955 (no. 1) cable, and eight in the 1956 (no. 2) cable.

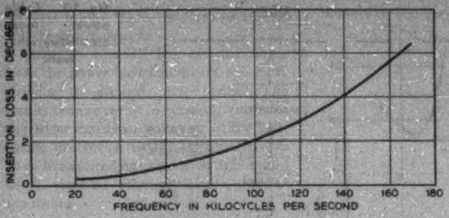

Fig. 7 (above). Transmitting deviation equalizer: loss-frequency characteristic

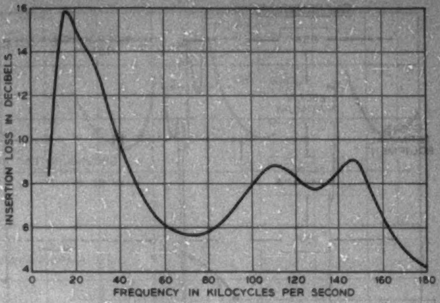

Fig. 9 (right). Receiving fixed equalizer: loss-frequency characteristic

The result of all the precautions taken to control initial misalignment was, in the 1955 cable, to hold the initial level difference between highest-level and lowest-level repeaters to about 6 db near the top frequency and to values between 4 and 9 db at lower frequencies, the 9-db value occurring in the range 50 to 70 kc where there is noise margin. In the 1956 cable, the level difference was about 4 db at the top frequency, and from 2 to 7 db elsewhere in the band.

SHORE EQUALIZATION

The equalization to be provided at the transmitting and receiving ends of the North Atlantic link had these primary functions:

1. For signal-to-noise reasons, to provide a signal level approximately flat with frequency on the grid of the third tube of the undersea repeaters.
2. To equalize the system so that the received signal level is approximately constant over the transmitted band.
3. To keep the system net loss flat, regardless of temperature variations in the ocean. (A change of 1 F in sea-bottom temperature would cause the cable loss to change by 2.8 db at 160 kc, and less than this at lower frequencies. The amplifiers are relatively unaffected by small temperature changes.)
4. To provide overload protection for the highest-level repeater.
5. To incorporate some adjustment against possible cable aging.

A portion of the transmitting terminal is shown in block schematic form in Fig. 4. All of the equalizers are constant resistance, 135-ohm unbalanced bridged-T structures. Their functions follow:

Low-pass Filter

The low-pass filter transmits signals up to 164 kc, and suppresses by 25 db or more, signals in the frequency range from 165 to 175 kc. Its purpose is to prevent an accidentally applied test tone from overloading the deep-sea repeaters should such a tone coincide with the resonance of the crystal used in a repeater for performance checking. The gain of a repeater to a signal applied at the resonance frequency of its crystal is about 25 db greater at 164 kc.

Transmitting Temperature Equalizer

It was estimated that the cable loss change from temperature variations would not exceed ±5 db at the top of the transmitted band. The change in cable loss versus frequency due to temperature variations is approximately the same as if the cable were made slightly longer or shorter, and so the temperature equalizer was designed to match cable shape. Temperature equalizers are used both in the transmitting and receiving terminals to minimize the signal-to-noise degradation caused by temperatures misalignment. Each equalizer provides a range of about ±5 db at the top of the band, the loss being adjustable in steps of 0.5 db by means of keys; see Fig. 5.

This range might appear to be more than necessary but it must be borne in mind that the sea-bottom temperature data left much to be desired in precise knowledge of both average and range.

Transmitting Equalizer

The transmitting equalizer was so designed that, with the temperature equalizer set at mid-range and with repeaters that match the cable loss, the signal level on the grid of the output tube of the first repeater would be flat with frequency. The loss-frequency characteristic is shown in Fig. 6.

Deviation Equalizer

The transmitting deviation equalizer is used to protect the highest-level repeater from overload. The design is based on data obtained during the laying, indicating which repeater was at the highest level at the various frequencies. The characteristic of this equalizer is shown in Fig. 7.

A portion of the receiving terminal is shown in block schematic form on Fig. 8. The generalized function of the equalizers is to make the signal level flat versus frequency at the input to the receiving amplifier no. 2.

The specific functions of the various equalizers are described in the following paragraphs.

Cable Length Equalizer

In planning the system, an estimate was made of how far the last repeater (receiving end) would be from the shore. Considerations of interference and level dictated a maximum distance not exceeding approximately 32 miles. For protection against wave action, trawlers, and similar hazards, the repeater should be no closer than about 5 miles. To take care of this variation, a cable length equalizer was designed that is capable of simulating the loss of 10 miles of cable, adjustable in 0.5-db steps at the top of the frequency band. Two of these could be used if needed. Once a system is laid, this equalizer should require no further adjustment unless it is used to take care of cable aging or a cable repair near shore.

Receiving Fixed Equalizer

The receiving fixed equalizer is the mop-up equalizer for the system. A final receiving equalizer, Fig. 9, has been constructed for the first crossing. Another, tailored to the no. 2 cable, will be designed on the basis of data taken after completion.

Receiving Temperature Equalizer

The receiving temperature equalizer is identical with the transmitting temperature unit.

Operational Design

General

The operational design of a transmission system considers the supplementary facilities which are needed for operation of the main transmission facility, for its supervision, and for its maintenance. In the present instance, these facilities include the cable station power plants for driving the carrier terminals and high-frequency line; the carrier terminals themselves and their associated carrier supply bays; the telephone and telegraph (speaker and printer) equipments needed for maintenance, supervision and administration of the over-all facility; the pilots, protection devices and alarms; and the maintenance and fault-locating equipment.

Power Supplies

With the exception of the plants for cable current supply, the power plants at Clarenville and Oban are relatively conventional, and follow telephone office techniques which are standard for the telephone administration of the particular side of the Atlantic on which they are located. They will not be discussed here, although it might be well to point out that, for the Bell equipment the supply is direct current, obtained from floated storage batteries, while at Oban, the supply for the Post Office equipment is alternating current from rotary machines driven normally from the station a-c supply, with storage battery backup.

The cable current supplies for the North Atlantic link[2] are complex and highly special. It is pertinent to discuss here briefly the requirements which beget this complexity. To assist in this, an elementary schematic of the cable power loop is shown in Fig. 10.

The main requirements that governed the design of these plants are:

1. Constant maintenance of uniform and known current in the power loop.
2. Protection of HF (high-frequency) line against faults induced by failures in power bays.
3. Protection of HF line against damage from power voltage surges caused by faults in the line itself.

Maintenance of constant and known operating current in the line is very important from the standpoint of system life because of the dependence of the rate of electron tube aging on the power dissipated in the heaters.[12]

The principal factor which tends to cause variations in the line current is the earth potential, which may appear between the terminals of the system. This potential may be of varying magnitude and of either polarity. Consequently, it may either aid or oppose the driving potential applied to a particular cable. The power circuit regulation is such that the presence of an aiding potential will be completely compensated, while opposing potentials will be compensated only to the degree possible with the maximum of 2,500 volts applied by the terminal plants. Beyond this point, the line current will be allowed to drop, so as to avoid excessive potential across the power separation filter capacitors in the shore-end repeaters.

Line faults caused by failures or misoperation of the power supplies must be carefully guarded against. Such failures might result in surges on the line, or excessive voltage or current. Protection against surges takes the form of inductors in the terminal power separation filters, which limit the rate of current change to tolerable values.

Failure of the capacitor in these filters could also create dangerous surges. The

Vol. 7
Pt. 1
1956

protection here takes the form of a large voltage design margin.

Faults in the HF line of importance from the power feed standpoint are short circuits to ground, and opens. The former tend to result in excessive currents; the latter excessive voltages. Very fast-acting protection in the terminal power bays is required to cope with these, and series electron tube regulators provide the means.

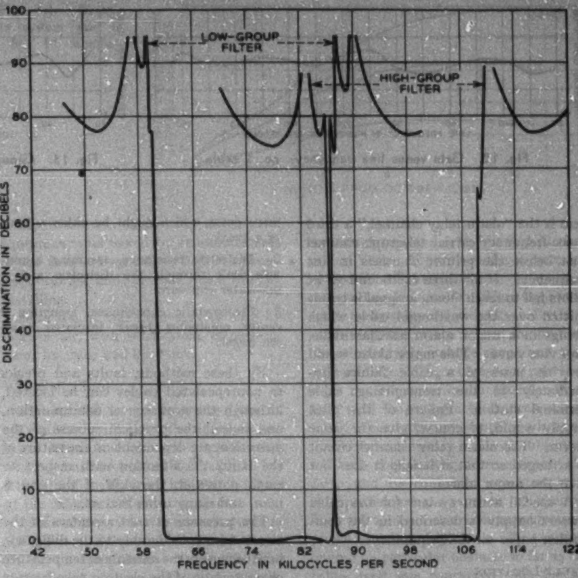

Fig. 11. Splitting filters: loss-frequency characteristic

TERMINAL PLAN

The plan of design of transmission terminal equipment, shown in Fig. 2 was based on the following objectives:

1. Use of standard, or modified standard equipment as far as possible.
2. To facilitate supply and maintenance of standard equipment, use of Bell System equipment in North America and Post Office equipment in the United Kingdom.
3. Provision of full duplicate equipment and means for quick shift between regular and alternate.
4. Provision of special equipment to fit Canadian requirements.
5. Provision of ample order-wire (speaker and printer) equipment, partly because there is no alternate undersea route.
6. Provision of no automatic loss regulation, because the loss changes are so slow; provision of three pilots as a basis for manual regulation.

Much of the equipment is standard. This includes group modems, group connectors, pilot supply, frequency-shift telegraph equipment for printer circuits, etc. Supergroup modulators are modified standard coaxial carrier equipment. The channel modems for speaker and printer circuits are a combination of type-*C* open-wire carrier active equipment, and filters designed for a military carrier system. The transmitting output amplifier is a modified version of one used in the Havana-Key West submarine cable system: the modifications include broader frequency band, lower modulation, and sharper overload cutoff. As in the coaxial carrier system, hybrid coils are provided at points in the Bell equipment where quick patching is needed.

The agreed Canadian bandwidth quota is 26 kc,[1] corresponding to $6\frac{1}{2}$ message telephone channels. The split between the $6\frac{1}{2}$ Canadian channels and the remaining $5\frac{1}{2}$ U. S. channels in the "split group" was accomplished by specially designed group-frequency splitting filters, with very sharp cutoff. The loss-versus-frequency characteristics of these filters are shown in Fig. 11. The resulting Canadian-half telephone channel next to the cut-apart was broad enough to accommodate 12 frequency-shift telegraph channels with 120-cycle carrier telegraph spacing. It is planned to use one of these for automatic regulation of the other 11. The U. S.-half channel is at present unassigned.

Two telephone order wires (speakers) and two teletypewriter order wires (printers) are provided for maintenance and administration purposes.

The two speakers occupy a 4-kc telephone channel which is the lower side band of 20 kc on the line. The 4-kc band is divided into halves by Bell type-*EB* split-channel equipment, which yields two narrow-band telephone channels. One of these is reserved for a "local" Clarenville-Oban circuit, available at all times to the personnel at these terminals. It constitutes a cleared channel which could be of great benefit in emergencies which might arise. The other narrow-band telephone channel, the "omnibus speaker," is extended through to other control points including the system metropolitan terminals.

The two printer circuits are frequency-shift voice-frequency telegraph channels, occupying line frequencies just below 16 kc. These are both brought to direct current at Clarenville and Oban, and extended by carrier telegraph to the metropolitan terminals. One is normally a "through" circuit with teletypewriters at the metropolitan terminals only, and the other is an "omnibus" circuit with teletypewriters connected at Oban, Clarenville, and other control points, permitting message interchange between all connected points.

Ninety-two-kc group frequency pilots are transmitted over the Clarenville-Oban link only, and blocked at its ends. The line frequencies corresponding to the 92-kc group frequencies are 52, 100, and 148 kc. These pilots are used for manual regulation and maintenance of the Clarenville-Oban link. Information derived from them governs the manual setting of the temperature equalizers. The sending power of the 92-kc pilots is regulated to within ±0.1-db variation with time.

Group frequency pilots of 84.080 kc also appear on this link. These, however, are system pilots applied at the metropolitan terminals. They are useful for evaluation of over-all system performance and for quickly locating transmission troubles.

Alarms are provided in the manner usual for multichannel telephone systems. A special feature of the pilot alarm sys-

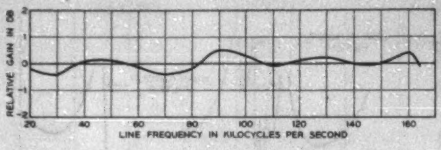

Fig. 12. Gain versus line frequency: no. 1 cable

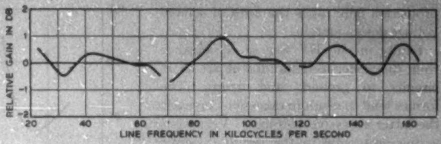

Fig. 13. Group-to-group frequency response: no. 1 cable

tem is the "alarm relay channel," a third voice-frequency carrier telegraph channel just below the printer channels in line frequency. If all three eastbound 92-kc pilots fail to reach Oban, a signal is transmitted over the westbound cable which brings in a major alarm at Clarenville, and vice versa. This major alarm would provide news of a cable failure immediately to the transmitting cable terminal station. Failure of the pilot supply would, of course, give the same alarm. The alarm relay channel circuit is arranged so that if it fails it does not give the major alarm.

A special alarm system for the cable current supply is described in the companion paper on that equipment.[3]

FAULT LOCATION

Length and inaccessibility have always imposed difficult requirements on fault-locating techniques for undersea cable systems. Before the advent of repeatered systems, much effort was expended on use of impedance methods, i.e., those involving resistance and electrostatic capacitance measurements to locate a fault to ground, or a break. (In the literature, "fault location" is a generalized term encompassing the field. A "fault" is an exposure of the cable conductor to the sea without a break in the conductor. A "break" is an interruption of the conductor with or without exposure to the sea.) Some work has been done also on magnetic pickup devices towed along the route by a ship.

With the advent of undersea repeaters, the problem has become even more difficult, both because of the effect of the repeater elements on impedance measurements, and because a fault may interrupt transmission without affecting the d-c loop. It has been necessary therefore to reassess the whole problem of fault location.

LOCATION OF FAULTS AFFECTING THE D-C POWER LOOP

Three types of measurement are made on submarine cables at present:

1. Center conductor resistance, assuming a short circuit or a sea-water exposure at some point, which might be either a fault or a break.
2. Dielectric resistance, assuming a pinhole leak through the dielectric and a sea-water exposure.
3. Electrostatic capacitance, assuming a center conductor break insulated from sea water.

By these methods, faults and breaks in nonrepeatered cables can be located, although the accuracy of determination, and indeed the practical success of the operation, are dependent on the nature of the fault, the situation with respect to earth potential, the skill of the craftsman, and many other factors.

The presence of cold repeaters in the circuit adds considerably to the difficulty, both because of the resistance/temperature characteristic of the electron tube heaters (153 in series with each cable) and because of polarization effects exhibited by the castor oil capacitors in the transatlantic repeaters. The capacitors have a storage characteristic which varies with the magnitude of applied voltage, the duration of its application, and the temperature.

Because of this, the usual methods of fault location are expected to give results of doubtful accuracy and so a new approach is being made to the problem. The results of the work are beyond the scope of this paper.

LOCATION OF TRANSMISSION FAULTS

The previous section deals with the situation where the d-c power loop has been opened or disturbed. Of equal importance is the location of transmission faults when the power loop is intact.

For this purpose, use is made of the discrete frequency crystal provided in each repeater.[6] This crystal is effectively in parallel with the feedback circuit of the amplifier, and at its resonant frequency the amplifier has a noise peak of the order of 25 db, with an effective noise band of about 4 cycles. When one repeater fails, it is possible to recognize the noise peak of each amplifier from the receiving end back to the failed unit. The noise peaks from the faulty unit and all preceding amplifiers will be missing, indicating location of the trouble. Noisy amplifiers can be singled out by an extension of the technique.

TESTING AND MAINTENANCE

Routine testing and maintenance activities at Oban and Clarenville can be divided into four parts: for the carrier terminals, for the station power equipment, for the cable current power units, and for the HF line. Usual methods apply, and the usual types of existing test equipment were provided with one exception.

The exception is a newly designed transmission measuring system. The system employs a decade-type sending oscillator with continuous tuning over the final 1-kc range. Provision is built in for precise calibration of output level. The receiving console contains a selective detector functioning as a terminating meter of 75-ohm input impedance, and can measure over the range −120 dbm to 0.00 dbm. Repeating coils are furnished to permit measurement on 135-ohm circuits. The detector can be calibrated for direct reading when used as a terminating meter.

The system covers a frequency range of 10 kc to 1.1 megacycles. It is useful therefore for measuring much of the standard British- and U. S.-designed carrier terminal equipment, as well as for normal line transmission measurements over both the North Atlantic and Cabot Strait (Newfoundland–Nova Scotia) submarine lines.

A special transmission measuring set is provided in the receiving console which facilitates measurements in the crystal frequency region 166 to 175 kc. As an oscillator, it is capable of delivering an output of up to +8 dbm into a 75-ohm load, with exceptional frequency stability and finely adjustable, motor-driven tuning. This is useful in locating and measuring the narrow-band response peaks of individual repeater crystals. The oscillator frequency is varied in the region of a particular peak, and the received power is measured at the peak frequency and at near-by frequencies. At the peak frequency, the crystal removes nearly all feedback in the repeater. Changes in repeater internal gain can thus be determined from shore.

As a detector, the set can measure from −110 dbm to −60 dbm in a bandwidth of about 2 cycles. This enables it to measure crystal noise peaks which may be spaced as closely as 50 cycles apart. To reduce the random variations in such narrow-band noise, a "slow integrate" circuit, of the order of 10 seconds, is provided. Thus the crystal noise peaks can be compared in magnitude with the system noise level at closely adjacent frequencies.

Assembly and Test of System

General

Assembly and initial testing of the North Atlantic link occupied a span of about 3 years. Because of the geographical and political factors involved, the job was a difficult one and it required close co-operation among individuals in many different organizations on both sides of the ocean.

Clarenville

The cable station at Clarenville houses the carrier terminal, cable-terminating, and power equipment at the junction of the North Atlantic and Cabot Strait links. It was designed by U. S. architects from requirements furnished by American Telephone and Telegraph Company engineers and was approved by the other parties to the enterprise. The building was constructed by a Canadian firm under the supervision of a Canadian architect. The equipment was put in place and connected by installers of the Northern Electric Company and tested by representatives of Bell Telephone Laboratories, Eastern Telephone and Telegraph Company, Northern Electric Company, and the British Post Office.

As Newfoundland is an island, shipments of equipment and supplies to Clarenville were carried by sea or air to St. John's, where they were trans-shipped by rail to Clarenville.

Oban

The cable station at Oban was executed by British contractors from designs drawn up by the British Post Office. Its equipment was installed by a British electrical contracting firm. Two Western Electric Company installers were present at Oban during the installation of the American-made cable terminating equipment and of the cable current supply bays, to provide necessary liaison and interpretation of drawing requirements. The Oban equipment was tested by representatives of the British Post Office, Bell Telephone Laboratories, and the firm which did the installing.

Here too, it was necessary to ship by boat or air, with subsequent trans-shipment by train and by truck.

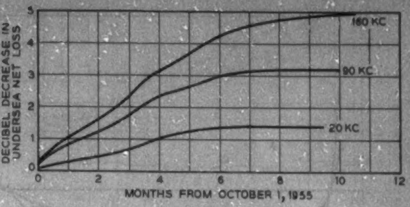

Fig. 14. Change in system gain in first 11 months

Undersea Link

Perhaps the most interesting phase of all was the handling of the undersea section. The actual laying is described elsewhere,[11] but much effort was required before the cable ship ever left the dolphins at the cable manufacturing plants.

Most of the cable was manufactured at the plant of Submarine Cables, Ltd., at Erith, on the Thames about 15 miles downstream from London. A smaller quantity of cable was manufactured by Simplex Wire and Cable Corporation at its plant in Newington, N. H. As the cable was completed, it was coiled in repeater section lengths in huge tanks. The ends of each repeater section were left available at a "splicing platform" where the repeaters, manufactured by Western Electric Company at Hillside, N. J.,[12] were spliced in. Spliced repeaters were located in water-filled troughs for protection against overheating while testing.

All repeaters were armored by Simplex at Newington. This involved their transportation by truck from the Western Electric shop at Hillside, where the flexible repeaters were manufactured, to Newington. While this sounds simple, it was actually a very carefully planned and controlled operation because of the need to avoid subjecting the units to any but the most necessary and unavoidable hazards. Consequently, the truck used for the purpose was specifically selected for size and construction, and was provided with a heating unit in the body. The route was carefully surveyed in advance for unusual hazards, and the truck speed was limited to a very modest value.

After the repeaters were armored, those to be incorporated in Simplex-made cable were spliced at Newington. Those destined for application in British-made cable were shipped by truck, following the same precautions, to Idlewild Airport in New York. From there they proceeded by special freight plane, one or two at a time, to London Airport. Here they were again trans-shipped by truck, to Erith.

The repeaters were housed in shipping cases[13] of a very strange shape and considerable size. These cases were provided with maximum-minimum thermometers and with impactograph devices which would record the maximum acceleration to which the repeaters had been subjected.

When ship-loading time arrived, the cable and its contained repeaters were transported over a system of sheaves from the tanks of the cable manufacturer to the tanks on shipboard. This process offered no particular obstacle so far as the cable itself was concerned, but the requirement against unnecessary bending of the repeater meant that a great deal of special attention had to be given to avoiding unnecessary deviations from a straight run, and to lifting the repeaters around sheaves where the direction of the loading line changed materially. Auxiliary protection was provided on each repeater in the form of angle irons with flexible extensions on each end which served to restrict any bending to the core tube region of the repeater, and safely limited the magnitude of the bends in this region.[11] One further precaution was observed, that of energizing the repeaters during the loading process. This accomplished two things. First, it permitted continuous testing; second, it reduced the hazards of possible damage to the electron tubes during loading, as the tungsten heaters are much more ductile when hot and the glassware of the tube is more resistant to shock and vibration.

System Performance

General

At the time of writing, the no. 2 cable has just been laid, but the no. 1 cable has had 11 months of successful life under test, a preservice period of probably greater duration than has been granted to any land system of comparable length and cost. It has been under constant ob-

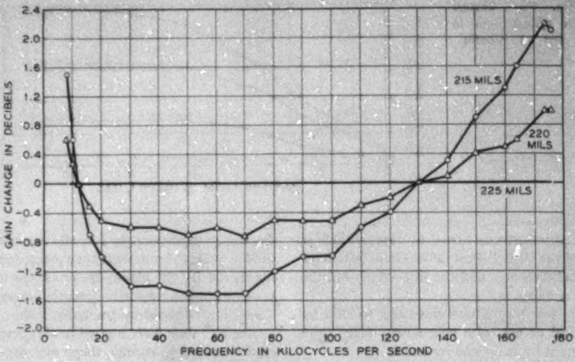

Fig. 15. Effect of cable current on system gain: no. 1 cable

servation and test, largely by the people who will operate it when it goes into service. The preservice measurements have been much more extensive in quantity and scope than the routine tests which are being made now that the system is in service.

Net Loss Tests

Net Loss Versus Frequency

Results of measurements in June 1956 on the no. 1 cable are shown in Figs. 12 and 13. The former covers the equalized HF line. Fig. 13 gives the corresponding group-to-group frequency response of the deep-sea link. These frequency characteristics will vary a little from time to time, depending partly on the change since the last adjustment of the temperature equalizer.

Note that while the slope in gross cable loss between 20 and 164 kc is about 2,100 db, the net loss of the equalized HF line over this band varies only about one db.

Net Loss Versus Time

The net loss of the undersea system (cable plus repeaters) has decreased slowly since the system was laid. The decrease is approximately cable shape, proportional to the square root of frequency. In 11 months, it has amounted to about 5 db at the top frequency. In the early months, the change was almost directly proportional to time, but later the rate slowed, as shown in Fig. 14.

The changes shown in the figure are due partly to change in cable temperature and partly to slow aging of the cable. Detailed studies of repeater crystal frequency changes have resulted in only an approximate separation into temperature effects and aging. However, it seems reasonable to assume that at the end of a 1-year cycle there would be little, if any, net change in the cable temperature averaged over the whole cable length. The greatest possibility of change would be in the shallow-water sections, and crystal measurements indicate that at the end of a year the average temperature of the shallow-water sections returned nearly to its initial value. Hence about 5 db seems chargeable to one year's aging. Extrapolation into the future, however, is uncertain. Theoretical considerations led to the idea that the rate of cable aging should decrease.

Information on long-term changes in transmission loss of earlier cables is very limited. The Havana–Key West cables were accurately measured just after laying, and again 5 years later. The change in that system from aging is very small, if indeed there is a change. That cable is generally like the transatlantic one, though it is smaller and has perhaps a significant difference in construction of the central conductor.

The foregoing applies to the net loss of the undersea part of the system only. The group-to-group net loss variation with time of the Clarenville-Oban link has been held within a much smaller range by temperature equalizer adjustments. Practices have been worked out which it is believed will hold the in-service variation with time to a fraction of a decibel.

Net Loss Versus Carrier Frequency Power Level

Single-frequency tests of carrier frequency output power versus input test power were made, up to a test power a little below the estimated overload of the highest-level repeater. An increase of 0.1 db in system net loss occurs at a power 2 to 3 db below the load limit of the transmitting amplifier. This is about 15 or 16 db above the expected rms value of the in-service system busy-hour load. The 0.1-db change is presumably due to the cumulative effect of smaller changes in several of the undersea amplifiers.

Net Loss Versus D-C Cable Current

Changes in cable current affect the repeater gain to a slight extent, the amount depending on the magnitude and phase of

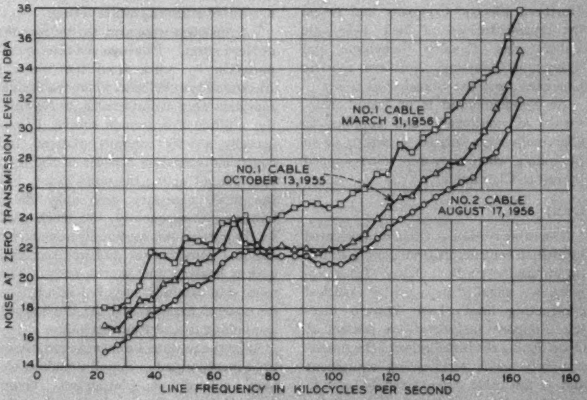

Fig. 16. Cable system noise

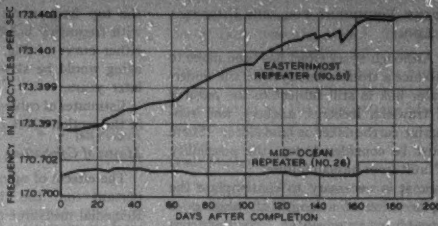

Fig. 17. Resonant frequency versus time: shore and deep-sea crystals

the feedback in the repeater as a function of frequency. Measured changes in the loss of the 2,000-mile system, for currents of 5 and 10 milliamperes less than the normal value of 225 milliamperes, are shown in Fig. 15. Under normal conditions the automatic control will hold the cable current variation within ±0.5 milliampere.

The shape of the curve in Fig. 15 is almost the same as that computed in advance from laboratory measurements on model repeaters.

SYSTEM NOISE

Values of noise on the no. 1 cable system measured in the Fall of 1955 and again in the Spring of 1956, are shown in Fig. 16. The noise increase is compatible with the decrease in undersea system net loss during this period. To prevent overload, the loss in the transmitting temperature equalizer has to be increased as the undersea loss decreases; this lowers the levels of the various parts of the undersea system by various amounts.

The noise shown in the top channel exceeds the 36-dba objective by a small amount. The excess can be recovered, if necessary, by equalization and level changes in the terminals, without recourse to compandors.

Fig. 16 shows also the noise on the no. 2 cable system shortly after completion of laying. The noise is lower than on the no. 1 cable. This is because results of experience on the no. 1 cable were utilized in better choice of cable repeater section lengths, and in better equalization while the 1956 cable was being laid.

MODULATION TESTS

Two-tone modulation tests of second- and third-order products were made, with the use of a large number of successive frequency combinations. The highest-level modulation products were at least 60 db below the 1-milliwatt test tones, at zero transmission level. This is approximately the value computed before the system was laid. Most of the modulation products were down substantially more than 60 db. Probably various causes contributed to the good performance, including the effect of misalignment in lowering repeater levels, and small propagation-time differences which minimize in-phase addition of third-order products from successive repeaters.

TELEGRAPH TRANSMISSION TESTS

At present writing, telegraph tests have been made only on the printer (telegraph order wire) channels, and without a system multichannel load. With the proposed specific telegraph level (STL) of −30 db (i.e., telegraph signal of −30 dbm per telegraph channel at 0.00-db telephone transmission level), the telegraph distortion was too low to measure reliably; it was possible to send clear messages under test conditions with a signal 36 db weaker than this.

CRYSTAL TESTS

All of the peaks of noise at the crystal resonance frequencies were easily discernible.

The crystal gain values all lay in the range from 23.6 to 27.2 db, with 60% of them lying in the range from 25 to 26 db. Crystal gain, as used here, is the difference between the system gain at a repeater crystal frequency and the average of the gains at 50 cycles above and below this frequency; the latter value is approximately the gain if the crystal were absent. No significant changes in crystal gain have occurred in 11 months of system life, and none were expected. These measurements are to be continued over the years, as an indication of electron tube aging, as explained in the companion paper on the repeater.[6]

A series of measurements of the frequency of each of the 51 repeater crystals versus time has been made. (Any of these frequency determinations can be checked on the same day within ±0.1 cycle with the special test apparatus and techniques used.) The crystals were designed to be extremely stable in frequency, so that measurements on one repeater, made at the land terminal, would not be affected by the combined effect of 50 other crystals at 100-cycle spacings. The crystal frequency varies only about −1/2 cycle per degree F increase in sea-bottom temperature. The change in frequency due to crystal aging in 11 months undersea is considered to lie in the range 0.00 cycle to −0.4 cycle.

Although the crystals were not designed as sea-bottom temperature indicators and are within a repeater housing, it seems likely that with precise techniques and after further stabilization, some uniquely accurate information on change of sea-bottom temperature will be obtainable.

In accordance with previous oceanographic knowledge of sea-bottom temperature, the frequency changes have been larger in the crystals near shore. The greatest change has been in the repeater nearest Oban. This is about 17 miles from shore and in water only about 50 fathoms deep. Its frequency change, and that of a typical deep-sea repeater, are shown in Fig. 17.

Future Considerations

SPARE EQUIPMENT FOR CABLE STATIONS

In a system as far-flung geographically as this one, and as important, much thought must be given not only to the supplies needed for routine replacement of expendable items but also to major replacements necessitated by fire or other causes. Accordingly, a schedule of spare equipment has been established, divided into two groups: "shelf" and "casualty."

Shelf spares are carried in the station itself, and include items such as dial lights, electron tubes, and dry-cell batteries, which have limited life in normal service. These are maintained in the cable station in quantity estimated as adequate for 2 years of operation.

Casualty spares embrace those major, essential frames and equipments without which the system cannot be operated. There are two subdivisions: those which are in common use in the telephone plant and which are therefore available by "cannibalization," and those which are special to the project, like the cable-current supplies and the cable-terminating bays. The common-use items are not stocked as casualty spares. Spares of the special items have been built and are stored in locations remote from the cable stations. In event of catastrophe, these can be drawn out and flown as near the point of need as possible, for onward shipment by available means.

Spare Equipment for the Undersea Link

Although every effort has been made to produce a trouble-free system, the underwater link is still subject to the hazards of trawlers, icebergs, anchors, and submarine earthquakes or landslides. There must be considered, too, the possibility of fault from human failure.

So it is necessary to contemplate the replacement of a length of cable, or a repeater, or an equalizer. For such contingency, spare cable of the various armor types has been stored on both sides of the Atlantic. Spare repeaters and equalizers are also available.

In addition, a spare called a "repair repeater" has been stocked. Need for this arises from the fact that except in very shallow water, a repair cannot be effected without the addition of cable over and above the length which was in the circuit initially. The amount of cable which must be added is a function of water depth, the condition of the sea at the time of the repair, and the amount of cable slack available in the immediate vicinity of the point in question.

When excess cable is introduced in amount sufficient to reduce significantly the system operating margins, its loss must be compensated. Hence, the repair repeater is stocked.

A repair repeater is a 2-tube device, essentially like a regular repeater, though its impedances are designed to match the cable impedances at input and output ends. However, its gain is sufficient to offset only about 5.3 miles of cable. A second type of repair repeater is under consideration, to compensate for about 15 miles of cable.

Long-Term Aging

General

In a system with some 3,200-db gross loss at its top frequency between points which are accessible for adjustment, a long-term change in loss of only 1% would have a profound effect on system performance.

For this reason, the repeater design included careful consideration of net gain change over the years.[8] The degree of control over aging is such that in a period of at least 20 years, and perhaps much longer, the estimated change in 51 repeaters might total 8-db added gain at the top frequency. The gain variation with frequency would be proportional to either curve of Fig. 15, and the rate of aging would be slower in earlier than in later years.

Estimates of cable-aging are discussed in the section "Net Loss Tests."

Means of Combatting Aging

The effects of aging would become important on the top channels first. Remedial measures to improve signal-to-noise, especially in the top channels, include: possible increase of transmission level at input of the final transmitting and load-limiting amplifier in the transmitting terminal; predistortion ahead of this amplifier; compandors; increase of direct current; and undersea re-equalization in later years. This last would be very expensive, and so it is necessary to examine the possibilities of the other measures.

The penalty for increasing the transmission level at the input of the transmitting amplifier is more peak-chopping and modulation-noise, peaks. The improvement that could be realized in this way is probably fairly small.

Predistortion is accomplished by inserting ahead of the transmitting amplifier a suitable shaping network adjusted for gain in the top part of the band and loss at lower frequencies. A complementary network (restoring network) is placed at the receiving terminal. This measure would improve signal-to-noise in the uppermost part of the band and reduce it in lower channels which have less noise. Some 3-db improvement might be thus realized in the top channel.

Compandors would give an effective signal-to-noise improvement of up to about 15 db for message telephone service, but none for services such as voice-frequency telegraph. Compandors would be applied to those channels needing them. They halve the range of talker volume, but also double the transmission variations between compressor and expandor, and thus tend to require some increases in the over-all channel net loss. The program (music) channels are already equipped with compandors which use up a part of the obtainable advantage.

If the combination of such measures should net an effective message signal-to-noise improvement of 20 db in the top channel, this would counterbalance aging of some 28 db in this channel, provided the aging were uniformly distributed along the system length. Thus considerable aging could be handled without undersea modification.

Acknowledgments

A system of the complexity of the one described obviously results from teamwork by a very large number of individuals. However, no paper on this subject could be written without acknowledgment to Dr. O. E. Buckley, J. J. Gilbert and O. B. Jacobs, now retired from Bell Telephone Laboratories. All of the early and fundamental Bell System work on repeatered submarine cable systems, and the concept of the flexible repeater, came from these sources and from their co-workers. Mr. Gilbert and Mr. Jacobs have also contributed to the present project.

Repeater Design for the North Atlantic Link

T. F. GLEICHMANN A. H. LINCE M. C. WOOLEY F. J. BRAGA

Synopsis: Some of the considerations governing the electrical and mechanical design of flexible repeaters and their component apparatus are discussed in this paper. The discussion includes description of the feedback amplifier and the sea-pressure resisting container that surrounds it. Examples are given of some of the extraordinary measures taken to ensure continuous performance in service.

REPEATERS for use in transatlantic submarine telephone cable system had to be designed to resist the stresses of laying, and to withstand the great pressures of water encountered in the North Atlantic route. In anticipation of the need for such a long telephone system in deep water, development work was started more than 20 years ago on the design of a flexible repeater that could be incorporated in the cable and be handled as cable by conventional cable ship techniques. Successful completion, in 1950, of the design and construction of the 24-channel Key West, Fla.,–Havana, Cuba, system,[1] led to the adoption of similar repeaters designed for 36 channels for the North Atlantic link discussed in companion papers.[2,3]

Repeater transmission characteristics determine, to a large extent, the degree to which system objectives can be met. In this repeater, significant characteristics are:

1. *Noise and Modulation.* These were established by the circuit configuration and by the use of the conservative electron tube[4] developed for the Key West–Havana project.
2. *Initial Misalignment,* or mismatch of repeater gain and cable loss throughout the transmitted band of frequencies. A match within 0.05 db (decibel) was the objective. This affected both the design and the precision required in manufacture.
3. *Aging.* As electron tubes lose mutual conductance with age, repeater feedback decreases, repeater gain changes, and misalignment is affected. Decrease in feedback increases the gain at the higher frequencies so that the signal input must be reduced to prevent overloading, resulting in a signal-to-noise penalty. Gain increase is inversely proportional to the amount of feedback; in these repeaters, 33 to 34 db of feedback was the objective to keep this source of misalignment in bounds.

Because repeaters are inaccessible for maintenance, facilities are provided to enable the individual repeater performance to be checked from the shore end. This feature also permits a defective repeater to be identified in the event of transmission failure.

Repeater Unit

The repeater, for the sake of discussion, may be divided into two parts: 1. the repeater unit, which contains the electron tubes and other circuit components, and 2. the waterproof container and seals which house the repeater unit.

CIRCUIT

The circuit of the repeater unit is shown in Fig. 1. It is a 3-stage feedback amplifier of conventional design with the cathodes at a-c ground. The amplifier is connected to the cable through input and output coupling networks. Each coupling network consists of a transformer and gain-shaping elements and a power-separation inductor.

The coupling networks directly affect the insertion gain as do the two feedback networks. The design of these networks controls the insertion gain of the amplifier. The required gain (inverse of cable loss) is shown in Fig. 2. The 39-db shaping required between 20 and 164 kc is divided approximately equally among the input and output coupling networks and the feedback networks.

The interstage networks are of conventional design. The gain of the first interstage is approximately flat across the band. The second interstage has a sloping characteristic, the gain increasing with frequency. The gain shaping of these networks offsets the loss of the feedback networks so that the feedback is approximately flat across the band.

Plate and heater power is supplied to the repeater over the cable.[5] The plate voltage, approximately 52 volts, is obtained from the drop across the heater string. The d-c circuits are isolated from the container by the high-voltage blocking capacitors C_1, C_2, and C_3.

GAIN FORMULA

The circuit of Fig. 1 may be represented by a simplified circuit consisting of an input coupling network, a 3-stage amplifier, an output network, and a feedback impedance Z_β as shown in Fig. 3. From this figure it can be shown that the insertion gain of the repeater is given by[6]

$$e^{\theta}=\frac{2e^{\theta_1}e^{\theta_2}Z_c}{Z_\beta}\left(\frac{\rho_i\rho_o g_{mT}Z_1Z_2Z_\beta}{1-\rho_i\rho_o g_{mT}Z_1Z_2Z_\beta}\right) \qquad (1)$$

when $Z_\beta \ll g_{m3}Z_pZ_gZ_1Z_2 \gg (Z_o+Z_p)$ and where

$$\rho_i=\frac{Z_g}{Z_i+Z_g}$$

and

$$\rho_o=\frac{Z_p}{Z_o+Z_p}$$

are "potentiometer terms." The gain of the input network is defined as $e^{\theta_1}=V/E_i$; where V is the open-circuit voltage of the input network with E_i as the source, and the gain of the output network is defined as $e^{\theta_2}=i/I_1$. This expression may be put in familiar form by recognizing that $\rho_i\rho_o g_{mT}Z_1Z_2Z_\beta$ is $\mu\beta$, the feedback around the loop. Hence

$$e^{\theta}=\frac{2e^{\theta_1}e^{\theta_2}Z_c}{Z_\beta}\left(\frac{\mu\beta}{1-\mu\beta}\right) \qquad (2)$$

Equation 2 shows that the insertion gain of the repeater is the product of five factors, namely:

1. e^{θ_1}, the gain of the input network.
2. e^{θ_2}, the gain of the output network.
3. Z_c, the cable impedance.
4. Z_β, the feedback impedance.
5. $(\mu\beta/1-\mu\beta)$, the $\mu\beta$ effect term.

It should be noted that a number of simplifying assumptions have been made. For example, the effect of grid-plate capacitance has been neglected. In addition, the β circuit has been assumed to be a 2-terminal impedance whereas it is actually a 4-terminal network. However, in the passband and over a large part of the outband of the repeater, these simplifications give a very good approximation to the true gain of the repeater.

In the passband, $(\mu\beta/1-\mu\beta)$ is very nearly unity so that the gain controlling factors are e^{θ_1}, e^{θ_2}, and $1/Z_\beta$, assuming that Z_c is fixed.

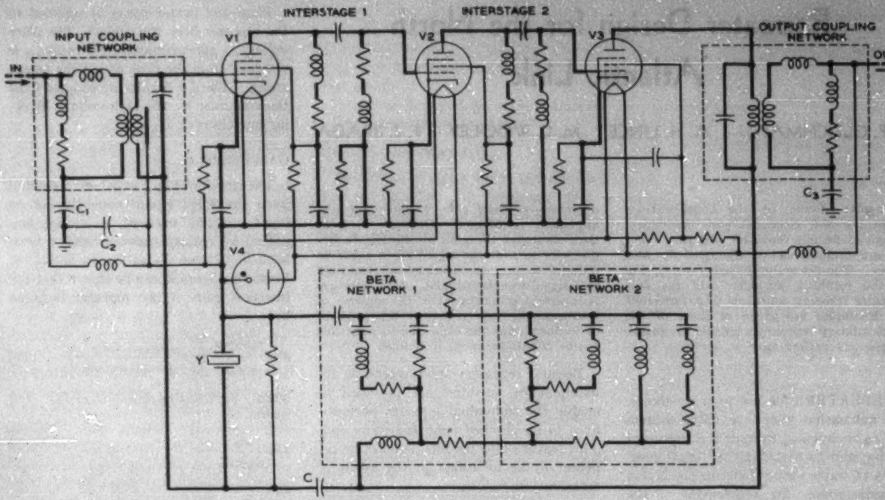

Fig. 1. Repeater schematic

COUPLING NETWORKS

The input and output networks are essentially identical. The networks are of unterminated design and therefore do not present a good termination to the cable at all frequencies, which results in some ripple in the system transmission characteristic at the lower edge of the band, and makes the repeater insertion gain sensitive to variations in the cable impedance. However, this arrangement has the advantage of maximum signal-to-noise performance, highest gain, and most effective shaping with a minimum of elements. A minimum of elements is important in view of the space restrictions imposed by the flexible repeater structure. The sensitivity of the gain to variation in impedance is minimized by close manufacturing control of the cable and networks.

The schematic of a coupling network is shown in Fig. 4, and the equivalent circuit in Fig. 5. Capacitor C_1 and inductor L_4 are part of the power-separation circuit. The effect of L_4 in the transmission band is negligible, and it has been omitted from the equivalent circuit. However, C_1 is in the direct transmission path and has a small effect at the lower edge of the band so that it becomes a design parameter. The combination R_2, L_2 controls the low-frequency gain shaping of the network. Inductor L_3 builds out the leakage inductance of the transformer and together with capacitor C_3 controls the shaping at the top end of the band. These elements are adjusted during manufacture of the networks to provide the desired shaping.

The equivalent circuit is an approximation to the true transformer circuit. By standard network analysis techniques the ratio V/E_1, the gain of the network, can be obtained. The agreement between measurements and computation is sufficiently close, several hundredths of a decibel, to ensure that the representation is good.

Each coupling network is designed to provide approximately one third of the total shaping required, or 13 decibels. While these networks are outside the feedback path, the impedances which they present to the amplifier are important factors in the feedback design. It can be seen from Fig. 3 that, at the amplifier input, the proportion of the feedback voltage which will be effective in producing feedback around the loop is dependent upon the potentiometer division between the grid-cathode impedance of the first tube and the impedance looking back into the coupling network. The greater the gain shaping of the network, the greater the potentiometer loss. The maximum gain which can be obtained from the coupling network is limited by the capacitance across the circuit. This capacitance cannot be reduced without increasing the potentiometer loss, and seriously limiting feedback. In this design, an acceptable compromise is made when the ratio of network capacitance to grid-cathode capacitance has been fixed at 1.2, as suggested by Bode.[8] The gain through the input network and the deviation from one-third cable shape is shown in Fig. 6. A typical potentiometer term is shown in Fig. 7.

Similar considerations apply to the output network with the further restriction that the impedance presented to the output tube should be about 40,000 ohms at the top edge of the band for optimum modulation performance.

The coupling networks have a temperature characteristic which must to taken into account in the insertion gain of the repeater. The characteristic is due to variations in the resistance of C_1 and R_2 with temperature. This amounts to 0.005 db per F (degree Fahrenheit) at 20 kc, decreasing with frequency and becoming negligible above 80 kc.

BETA CIRCUIT

The beta or feedback network is designed to complement the combined characteristics of the input and output coupling networks and mop-up residual effects, such as those due to $\mu\beta$ effect and coupling-network temperature coefficients. The network also provides the d-c path for the output-tube plate current.

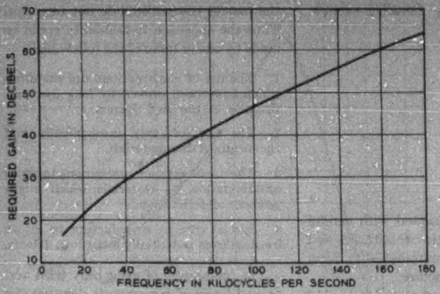

Fig. 2. Required insertion gain

The configuration of the beta circuit is shown in Fig. 8. In the passband it is a 2-terminal network whose impedance varies from about 300 ohms at 20 kc to 70 ohms at 164 kc. It consists of essentially two parts. The elements to the left of the dotted line provide the major portion of the shaping. With these, the repeater is within ±0.7 db of the required gain. The series resonant circuits to the right of the dotted line reduce this to the ±0.05-db set as the objective.

The mopping-up elements are connected to the main portion of the beta circuit through a resistance potentiometer R_1, R_2, and R_3. This scales the elements of the resonant circuits to values which would meet mounting space and component restrictions.

BUILT-IN TESTING FEATURES

The crystal *Y* and capacitor *C*, Fig. 1, in the feedback path provide the means for checking the repeater from the shore station. The crystal is a sharply tuned series resonant shunt on the feedback path, which reduces the feedback at the resonant frequency and thus produces a narrow peak in the insertion gain characteristic of the repeater. The feedback reduction, and hence the peak gain, is controlled by the potentiometer divider formed by the reactance of the capacitor and the series resonant resistance of the crystal. The crystal and capacitor are chosen so that substantially all the feedback is removed from the repeater. With no feedback, the peak gain is proportional to the mutual conductance of the three tubes.

At frequencies well off resonance, the impedance of the crystal is high so that no reduction in feedback results. Periodic measurements of gain, at the resonant frequency relative to measurements made at a frequency off resonance, will show any changes in the tubes. The crystal frequency is different for each repeater so that by measuring the gain from the shore stations at the various crystal frequencies it is possible to monitor the performance of the individual repeaters.

The increase in gain at the peak is approximately 25 db. The crystal frequencies, spaced at 100-cycle intervals, are placed above the normal transmitted band between 167 and 173.4 kc.

Thermal noise, always present at the input to the repeater, is also amplified over the narrow band of frequencies corresponding to the peak gain in each repeater, so that at the receiving end of the line there are a series of noise peaks, one for each repeater. Should a repeater fail, the noise peaks of all repeaters between the faulty repeater and the receiving end will be present and those from repeaters ahead will be missing. By determining which peaks are missing, the location of the failed repeater can be determined. It is obvious that to locate a faulty repeater the power circuit must be intact. To guard against power interruption owing to an open electron-tube heater, a gas tube *V*4, Fig. 1, is connected across the heater string as a by-pass.

LOOP FEEDBACK

The design of the feedback loop follows conventional practice. The restrictions that limit the amount of feedback that can be obtained in the transmitted band are well known.[6] Broadly speaking, the figure of merit of the electron tubes and the incidental circuit capacitances determine the asymptotic cutoff which limits the amount of feedback that can be obtained in the band. With the flexible repeater circuit, capacitances are rather large because of the severe space restrictions and physical length of the structure. Transit time of 1.8 degrees per megacycle per tube and a like amount for the physical length of the feedback loop reduced the available feedback by 2 db.

Margins of 10 db at phase crossover and 30 degrees at gain crossover were set as design objectives. While these may seem to be ultraconservative in view of the tight controls placed on components and the mechanical assembly, it should be borne in mind that the repeaters are inaccessible and repairs would be costly.

Modulation and tube-aging considerations require a minimum feedback of 33 to 34 db. With the restrictions noted previously and the effect of the potentiometer terms on the available feedback, the top edge of the band is limited to about 165 kc with the desired feedback.

MECHANICAL DESIGN

To provide a flexible structure the repeater unit is assembled in a number of longitudinal sections mechanically coupled by helical springs and electrically interconnected by means of bus tapes. The assembly is composed of 17 sections. Figs. 9 and 10 show the repeater make-up and an assembled unit.

g_{mT} = PRODUCT OF g_m OF THREE AMPLIFIER TUBES

Fig. 3. Simplified amplifier circuit

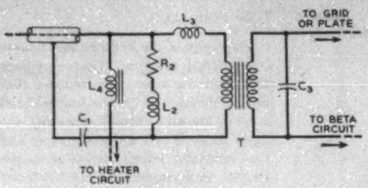

Fig. 4. Coupling network

The sections consist of the circuit component, or components, mounted in machined plastic forms and enclosed in a plastic container which is enclosed in a housing of the same material. The material used is methyl methacrylate which was chosen for its physical and chemical stability and good machinability. The sections contain circuit components, grouped functionally, such as input coupling network, interstage, electron tube, or high-voltage blocking capacitor. In the case of the feedback network it was necessary to mount the network in two sections because of the large numbers of components involved. A typical network, container, and housing are shown in Fig. 11.

The bus tapes are placed in grooves milled in the outer surfaces of the section containers. Wiring spaces are machined into the ends of the containers for connecting network leads to the bus tapes. The housing is placed over the container and the busses and is closed by a plastic coupler plate which also forms part of the intersection couplers. The coupler plates are fastened to the housing with plastic pins.

Between sections, the bus tapes are looped toward the longitudinal axis of the repeater unit. The dimensions of the loop are rigidly controlled so that, as the unit is flexed during bending of the repeater, the loops always return to their original location between sections and do not short to each other or the metal outer container. The bus tapes have either an electric connection or lock at one end of each section to eliminate any tendency of the tapes to creep as the repeater unit is flexed.

The busses consist of two copper tapes in parallel to guard against opens should one tape break. The design of the connections to the busses is such that once the section is closed there can be no disturbance of the tapes or network leads in the vicinity of the electric connections. The bus-type wiring plan was chosen as the best arrangement for the long structure in keeping with the stringent transmission requirements. Electrically adjacent but physically remote components can thus be interconnected with careful control of the parasitic capacitances and couplings to insure reproducibility from unit to unit in manufacture.

Components

The development of passive components for use in the flexible repeater presented a number of unusual problems, the most important being: 1. the extreme reliability, 2. the high degree of stability, 3. the limitations on size and shape, and 4. an environment of constant low temperature.

The repeaters for the transaltantic system contain a total of approximately 6,000 resistors, capacitors, inductors, and transformers. If we are to be 90% (per cent) certain of attaining the objective of 20 years, service without failure of any of these components, the effective average annual failure rate for the components must not be more than one in a million. To assure this degree of reliability by actual tests would require more than 400 years of testing on 6,000 components. Obviously, some other approach to insure reliability is required. The most obvious avenue, that of providing a large factor of safety, was not open because of space limitations.

Fortunately, with only one exception, the passive components do not wear out. Thus the approach to reliability could be made by one or more of the following:

1. The use of constructions and materials which have been proved by long use, particularly in the Bell System.
2. The use of only mechanically and chemically stable materials.
3. The use of extreme precautions to avoid contamination by materials which might promote deterioration.
4. Special care in manufacture to insure freedom from potentially hazardous defects.

The philosophy of using only tried and proved types of components dictated the use of wire-wound resistors, impregnated-paper and silvered-mica capacitors, and permalloy cores for inductors and transformers. While newer and, in some ways, superior materials are known, none of these possessed the necessary long record of trouble-free performance. In some cases, particularly in resistors, this approach resulted in more difficult design problems and also in physically larger components. While the ambient conditions in the repeater, i.e., low temperatures and extreme dryness, are ideal from the standpoint of minimizing corrosion or other harmful effects of a chemical nature, the materials used in the fabrication of components were nevertheless limited to those which are inherently stable and nonreactive. In addition, raw materials were carefully protected from contamination from the time of their manufacture until they were used, or, wherever possible, they were cleaned and tested for freedom from contaminants just prior to use. Unusually detailed specifications were prepared for all materials.

The effort to achieve extreme reliability also influenced or dictated a number of

design factors such as the minimum wire diameters used in wound apparatus, the use of as few electrical joints as possible, and the use of relatively simple structures. These limitations resulted in the use of unencased components in most instances. Wherever possible, the ends of windings were used as terminal leads to avoid unnecessary soldered connections. This injected the additional hazard of lead breakage owing to handling during manufacture and inspection. This hazard was minimized in most instances by providing the windings with extra turns which were removed just before the component was assembled in the network. Thus, the lead wires in the final assembly had never been subjected to severe stress. Where this technique was impracticable, special fixtures and handling procedures were used to prevent undue flexing or stressing of lead wires.

As mentioned previously, there was one type of passive component in which life is a function of time and severity of operating conditions. These are the capacitors, especially those subject to high voltages. Because of this and the fact that the physical and electrical requirements dictated the use of relatively high dielectric stress in these capacitors, a program of study covering a wide range of dielectric materials was undertaken about 1940. This study showed that none of the usual solid or semisolid materials used to impregnate paper capacitors were suitable for continuous use at sea-bottom temperatures. Typical results of this program are shown in Figs. 12 and 13. These curves show the performance of capacitors operating at approximately 1.8 times normal dielectric stress at both sea-bottom and room temperatures. It is evident that even semisolid impregnants are inferior to liquids at the lower temperature. The need for the maximum capacitance in a given space restricted the field still further, so that the final choice was a design using castor-oil-impregnated kraft paper as the dielectric.

It is well established that the life of impregnated-paper capacitors is inversely proportional to the fourth to sixth power of the voltage stress or

$$\frac{L_1}{L_2}=\left(\frac{V_2}{V_1}\right)^p$$

where p ranges from 4 to 6. This fact permits the accumulation of a large amount of life information in a relatively short time. To insure that the capacitor design selected would provide the degree of reliability required, a number of capacitors were constructed and placed on test at voltage stresses ranging from $1^1/_2$ to $2^1/_4$ times the maximum stress expected in service. From the performance of these samples, a prediction of that under service conditions can be made as follows.

The total equivalent exposure, in terms of capacitor years at the maximum service voltage, can be computed for the samples under test by the following summation

$$T=N_1T_1\left(\frac{V_1}{V_s}\right)^p+N_2T_2\left(\frac{V_2}{V_s}\right)^p+\dots+ N_rT_r\left(\frac{V_r}{V_s}\right)^p \quad (3)$$

where N_1, N_2, … N_r are the number of samples on test at voltage stresses V_1, V_2, V_r; and T_1, T_2, … T_r are the total times of the individual tests, and V_s is the maximum voltage stress under service conditions.

If, as has been the case in the tests described, there has been only one failure in the total exposure T, we can estimate, from probability equations, the limits or bounds within which the first failure will occur in a system involving a given number of capacitors, operating at a voltage stress V_s. These equations are probability of no failures in exposure

$$T=e^{-(T/L)} \quad (4)$$

probability of more than one failure in exposure time

$$T=1-\left(1+\frac{T}{L}\right)e^{-T/L} \quad (5)$$

where T is obtained from equation 3, and L is the total exposure in the same units as T for the service conditions. The solutions of equations 4 and 5 for L, using any desired probability, give the maximum and minimum exposures in capacitor-years, within which the first failure may be expected to occur under service conditions.

However, since the voltage on the capacitors varies from repeater to repeater, it is necessary to determine the equivalent exposure of the system, in terms of capacitor-years per year of operation at the maximum service voltage, to estimate the time to the first failure in the system. This is obtained from equation 3, for one half of one cable, by substituting the supply voltage at each repeater for V_1, V_2, etc., the maximum service voltage for V_s, and the number of capacitors per repeater for N. The total exposure for a 2-cable system is then four times this figure. With the data which have been accumulated and the number of capacitors and voltages of the transatlantic system, it is

estimated, with a probability of being correct nine times in ten, that the first wear-out failure of a capacitor in the transatlantic system will not occur in less than 16 years nor more than 600 years.

There is, of course, the possibility of a catastrophic or early failure due to mechanical or other defects not associated with normal deterioration of the dielectric. Such potential failures are not always detected by the commonly used short-time over-voltage test. Thus, for submarine cable repeaters, all capacitors subjected to d-c potentials in service are subjected to at least $1^1/_2$ times the maximum operating voltage for a period of 4 to 6 months before they are used in repeaters. Experience indicates that this is adequate to detect potential early failures. The results of this type of testing on submarine cable capacitors is an indication of the care used in selecting materials and manufacturing the capacitors. Only one failure has occurred in more than 3,000 capacitor-years of testing.

An important aspect of the control of quality of components is the control of the raw materials used in their manufacture. For the transatlantic project, this was accomplished by rigid specifications, thorough inspection and testing, supplemented in some cases by a process of selection.

This can be illustrated by the procedure used for selecting the paper which is used as the dielectric in capacitors. The Western Electric Company, Inc., normally inspects many lots of capacitor paper during each year. Those lots which were outstanding in their ability to stand up under a highly accelerated voltage test were selected from this regular inspection process. These selected lots were then subjected to a somewhat less highly accelerated life test. Paper which met the performance requirements of this test was slit into the proper widths for use in capacitors. Sample capacitors were then prepared with this paper and so selected that they represented a uniform sampling of the lot at the rate of one sample for approximately each 3 pounds of paper. These samples were impregnated with the same lot of oil to be used in the final product. Satisfactory completion of accelerated life and other tests on these samples constituted final qualification of the paper for production of capacitors. Relatively few raw materials were adaptable to such tests or required such detailed and exhaustive inspection as capacitor paper. But the attitude in all cases was that the material be qualified not only as to its primary constituents or characteristics, but also as to its uniformity and freedom from unwanted properties.

Fig. 9. Repeater make-up

To a considerable extent, stability of components is assured by the practice of using only those types of structures which have long records of satisfactory field performance. However, in some cases, a product far more stable than usual was required. This was true of the high-voltage capacitors, where other requirements dictated the use of impregnated paper as the dielectric, but where the degree of stability required was comparable to that expected of more stable types of capacitors. In so far as possible, stability was built into the components by appropriate design, but stabilizing treatments, consisting of repeated temperature cycles, were used where necessary to accelerate aging processes to reach a stable condition prior to the assembly of the repeaters. Temperature cycling or observation over periods up to 6 months were used also to determine that the components' characteristics were stable. Exceptional inspection procedures which were followed to insure reliability and stability are described in detail in a companion paper.[7]

As mentioned earlier, the design and construction of components was simplified by omitting housings or containers, except for oil-impregnated paper capacitors. Adequate mountings for the components were obtained in several ways. Mica capacitors were cemented to small bases of methyl methacrylate which were in turn cemented in suitable recesses in network structures. Inductors and transformers were cemented directly into recesses in the network housings. Fig. 14 illustrates some of these structures and their mounting arrangements. On the bottom is a molybdenum permalloy dust-core coil in which a mounting ring of methyl methacrylate, provided with radial fins, is secured around the core by tape and the wire of the winding. Such inductors were mounted by cementing the projecting fins into slots arranged around a recess in the network housing. On top is an inductor which, for electrical reasons, required a core of greater cross section than could be accommodated in the network when made by the usual toroidal construction. In this case, the effective cross section of two cores was obtained by cementing the cores in a figure-eight position and applying the winding so that it threads the hole in both cores. With these constructions, the cement used to secure the inductors does not come into contact with the wire of the winding, which is thereby not subject to strains produced by curing of the cement.

For economy of space and also to reduce the number of soldered connections, many of the components' structures con-

Fig. 10 (left). Over-all view of the repeater unit

Fig. 11 (right). Network section

tain two or more elements. Inductors and resistors were combined by winding inductors with resistance wire. Separate adjustment of inductance and resistance were obtained by adjusting turns for inductance and the length of wire in a small noninductive winding for resistance. The inductor on the bottom, in Fig. 14, illustrates one type in which the noninductive part of the winding is placed on one of the separating fins. In some cases, capacitors and resistors were also combined. Fig. 15 illustrates two of these. The capacitor at the lower right contains three capacitances and a single resistance in the same container. This requires that the resistor parts be capable of withstanding the capacitor drying and impregnation process, and also that the resistor contain nothing which would be harmful to the capacitor. The capacitor on the left, in this figure, is housed in a ceramic container on which is wound a resistor. The capacitor at the top is a high-voltage type which, aside from electron tubes, represents the largest single component used in the repeater. In this capacitor, the tape terminals which contact the electrodes are brought out through the ceramic cover and are made long enough to reach an appropriate point, so as to avoid additional soldered connections. Such special designs introduced many problems in the manufacture of the components. However, the improved performance of the repeater and the increase in the inherent reliability of the over-all system fully justified the greater effort which was required for the production of such specialized apparatus.

Power By-pass Gas Tube

The fault-locating means, referred to previously, requires that the power circuit through the cable be continuous. To protect against an open circuit in the repeater, such as a heater failure, an additional device is required to by-pass the line current. This by-pass must be a high resistance under normal operating conditions since any current taken by this device muse be supplied through preceding repeaters. If an open circuit occurs, the by-pass must carry the full cable current. At full current, the voltage drop should be small to avoid excessive localized power dissipation in the repeater. The device should recover when power is removed, so that false operation by a transient condition will not permanently by-pass the repeater.

A gas diode, using an ionically heated cathode, has been used to meet these requirements. By making the breakdown voltage safely greater than the drop across the heater string, no power is taken by the tube under normal repeater operation. In the event of an open circuit in the repeater, the voltage across the tube rises and breakdown occurs. Full cable current is then passed through the gas discharge. Removal of power from the cable allows the tube to deionize and recover in the event of false triggering by transients. The cathode is a coil of tungsten wire, coated with a mixture of barium and strontium oxide. A cold-cathode glow discharge forms when the tube is first broken down. This discharge has a sustaining voltage of the order of 70 volts. The glow discharge initially covers the entire cathode area. Local heating occurs and some parts of the oxide coating begin to emit electrons thermionically. This local emission causes increased current density and further increases the local heating. The discharge thus concentrates to a thermionic arc covering only a portion of the coil. The sustaining voltage is then of the order of 10 volts.

Mechanically, the tube was designed to minimize the possibility of a short circuit resulting from structural failure of tube parts. Fig. 16 shows the construction of the tube. The glass envelope and stem structure, which had previously been developed for the hot-cathode repeater tubes, were used as a starting point for the design. The anode is a circular disk of nickel attached to two of the stem lead wires. To provide shock resistance, the supporting stem leads are crossed and welded in the center. To protect against weld failure, a nickel sleeve is used at each end of the cathode coil. It is crimped to hold the coil mechanically in place and then welded at the end for electric connection. At the end of the coil as well as in all other places where it is possible, a mechanical wrap is made in addition to spot welding. An additional precaution is taken by inserting an insulated molybdenum support rod through the center of the cathode coil. The filling gas is argon at a pressure of 10 millimeters of mercury. To provide initial ionization, one microgram of radium, in the form of radium bromide, was placed on the inside of the tube envelope. All materials were procured in batches of sufficient size to make the entire lot of tubes and were carefully tested before being approved for use. The tubes were fabricated in small groups and a complete history was kept of the processing of each lot.

For detailed study of tube performance, a number of electrical tests were made. These involved measurements of breakdown voltage, operating voltage as a glow discharge at low current, current required to cause the transition to a thermionic arc, the time required at the cable current to cause transition to the low-voltage arc, and the sustaining voltage at the full cable current.

All tubes were aged by operating at 250 ma (milliamperes) on a schedule which included a sequence of short on-off periods, 2 minutes on, 2 minutes off, followed by periods of continuous operation. A total of 150 starts and 300 hr (hours) of continuous operation were used. Following this aging schedule, the tubes were allowed to stabilize for a few days and then subjected to a 2-hr thermal treatment or pulse at 125 C (degrees centigrade). It was required that no more than a few volts change in breakdown voltage occur during this thermal pulse before a tube was considered as a candidate for use in repeaters.

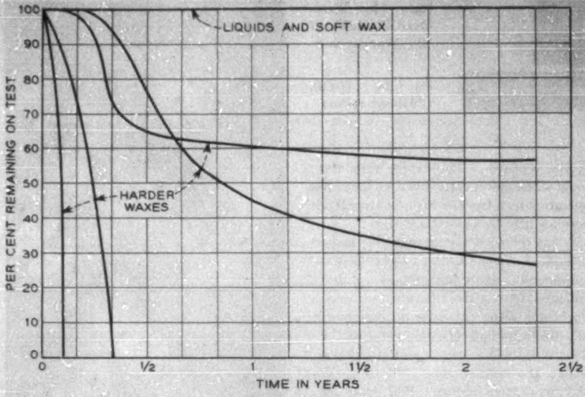

Fig. 12. Accelerated life tests on paper capacitors with various impregnants at room temperature 60 to 80 F

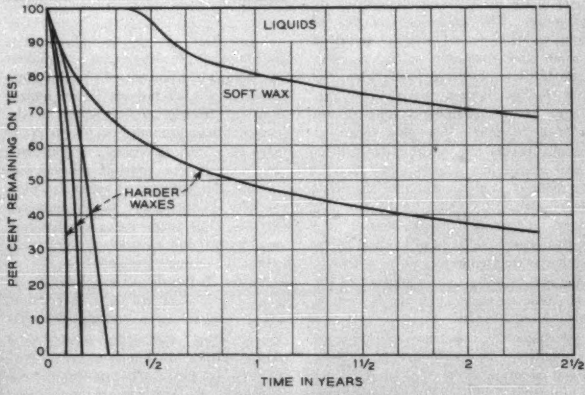

Fig. 13. Accelerated life tests on paper capacitors with various impregnants at 40 F

After aging and selection as candidates for repeaters, tubes were stored in a light-tight can at 0 C. Measurements were made to assure stability of breakdown voltage and breakdown time.

The quality of each group of 12 tubes was further checked by continuous- and on-off cycling life tests. The fact, that none of these tubes has failed on the cycling tests at less than 3,500 hr and 1,500 starts and no tube on continuous operation has failed at less than 4,200 hr, gives assurance that system tubes will start once and operate for the few hours necessary to locate a defective repeater. Long-term shelf tests of representative samples at 70 C and at 0 C give assurance of satisfactory behavior in the system.

Container and Seals

The design of the flexible enclosure for the flexible repeater unit is basically the same as it emerged from its development stages in the 1930's. It is virtually identical to the structure of the repeaters manufactured by the Bell Telephone Laboratories for the cables laid in 1950 between Key West and Havana.[1]

The functions of the enclosure are: 1. to protect the repeater unit from the effects of water at great pressure at the ocean bottom, 2. to provide means of connecting the repeater to the cable before laying, and 3. to be slender and flexible enough to behave like cable during laying. How these functions are met in the design may be more readily understood by reference to Fig. 17.

The repeater unit, described earlier, is surrounded by a 2-layer carcass of steel rings, end to end. The rings are surrounded in turn by a copper tube $1^3/_4$ inches in diameter and having a 1/32-inch wall.

When a repeater is bent during laying by passing onto the cable-ship drum, the steel rings separate at the outer periphery of the bend and the copper tube stretches beyond its elastic limit. As the repeater leaves the drum under tension, the rings separate and the copper stretches on the opposite side, leaving the repeater in a slightly elongated state. At the ocean bottom, hydraulic pressure restores the repeater to its original condition with rings abutted and the copper tube reformed.

The system of seals in each end of the tube consists of: 1. a glass-to-Kovar seal adjacent to the repeater unit, 2. a rubber-to-brass seal seaward from the glass seal, and 3. a core-tube and core-sleeve seal seaward from the rubber seal.

The glass seal, although capable of withstanding sea-bottom pressures, is primarily a water-vapor barrier and a lead through for electric connection to the repeater circuit. In service, it is normally protected from exposure to sea pressures by the rubber seal.

The rubber seal, capable of withstanding sea-bottom pressures, is indeed exposed to these pressures for the life of the repeater, but is not exposed to sea water. It is likewise a lead through for electric connection from the cable to the glass seal.

The core-sleeve seal is an elastic barrier between sea water on the outside and a fluid on the inside. This fluid, polyisobutylene, is a viscous honey-like substance, chemically inert, electrically a good insulator, and a moderately good water-vapor barrier. It fills the long thin annular space outside the cable core and inside a copper-core tube, and thus becomes the medium of transmitting to the rubber seal the sea pressure exerted on the core sleeve. It can be seen that the core-sleeve seal has nominally no pressure-resisting function and no electrical function.

The same fluid is also used to fill the space between the glass and rubber seals. Voids at any point in the system of seals

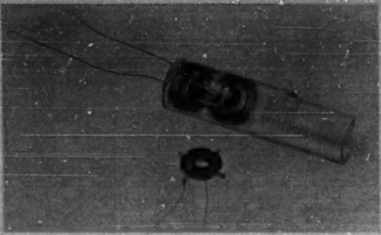

Fig. 14. Mounting for molybdenum permalloy dust-core coil

are potential hazards to long trouble-free life. Empty pockets, for instance, lying between the central conductor and the outer conductor, or container, are capable of becoming electrically conducting paths, if filled with water vapor. As pointed out in companion papers,[4,5] the voltage between the repeater and cable central and outer conductors is about 2,000 volts at the ends of the transatlantic system.

The filling of the seal interspace with a liquid would defeat one function of the rubber seal if special features were not provided in the rubber-seal design. Very slight displacement of the rubber seal toward the glass seal because of sea pressure, or resulting from reduction in volume because of falling temperature, would otherwise build up pressure in the liquid and on the glass seal. This is avoided by providing a kind of resilience in the interspace chamber. Three small brass bellows, partly compressed, occupy fixed cavities in the chamber. They can compress readily and maintain essentially constant conditions, independent of external pressures and temperatures.

The entire repeater assembly enclosed in copper is approximately 23 feet long. Tails of cable at each end make the total length about 80 feet before splicing. The central conductor of each cable tail is joined to the rubber-seal central conductor, with the insulation molded in place in generally the same manner as in cable-to-cable junctions elsewhere in the system. The outer-conductor copper tapes of the cable tails are electrically connected to the copper-core tubes.

The copper region is coated with asphalt varnish and gutta-percha tape to minimize corrosion. Over this coating, bandagelike layers of glass-fabric tape are built up to produce an outer contour tapering from cable diameter at one end up to repeater diameter, and back down to cable diameter at the opposite end. The tape covering is saturated with asphalt varnish. This tape is primarily a bedding for the armor wires that are laid on the outside of both cable tails and repeater to make the repeater cablelike in its tensile properties and capable of being spliced to cable.

In the region of the repeater proper where the diameter is double that of cable, extra armor wires are added to produce a layer without spaces. Also, to avoid subjecting the repeater to the torque characteristically present in cable under the tensions of laying, a second layer of armor wires of opposite lay is added over the first layer. This process is so closely related to the armoring of cable core in a cable factory that it is performed there.

MATERIALS

Following the same design philosophy applied to the repeater components, the materials of construction of the repeater container and seals were chosen for maximum life, compatibility with each other, and for best adaptability to the design intent. Specifications, particularly adapted to this use were set up for all of the some 50 different metals and nonmetals used in the enclosure design. In general, the methods established for proving the integrity of the materials are more elaborate than usual commercial practice. In most instances, such as that of copper container tubes, the extraordinary inspection for defects and weaknesses with its resulting rejection rate resulted in high cost for the usable material.

Testing

A substantial part of the development work on the repeater enclosure was concerned with devising tests that give real assurance of soundness and stability. It is beyond the scope of this paper to discuss how each part is tested before and after it is assembled, but certain outstanding tests deserve mention.

STEEL-RING TESTS

Each of the inner steel rings, before installation, is required to pass a magnetic-particle test to find evidence of hidden metallurgical faults. Each ring is later a participant in a group test under hydraulic pressure simulating the crushing effect of ocean-bottom service, but exceeding the working pressures. The magnetic-particle test is repeated.

HELIUM-LEAK TESTS

Both glass- and rubber-seal assemblies, before being installed in repeaters, are required to undergo individual tests

under high-pressure helium gas. Helium is used not only because its small molecules can pass through smaller leaks than can water molecules, but also because of the excellent mass spectrometer type of leak detectors commercially available for this technique. While helium is applied at high pressure to the outer wall of the seal, the inner wall is maintained under vacuum in a chamber joined with the leak detector. The passage of helium through a faulty seal at the rate of 10^{-9} milliliters per second can be detected. Stated differently, this is one milliliter of helium in 30 years. The relation of water-leak rate to helium-leak rate is dependent on the physical nature of the leak, but if they were assumed to be equal rates, the amount of water which might enter a tested repeater in 20 years would be 0.66 gram. A desiccant within the repeater cavity is designed to keep the relative humidity under 10% if the water intake were five times this amount.

After glass seals are silver brazed into the ends of the copper tube of the repeater, the helium test is repeated to check the braze and to recheck the seal. For this test the entire repeater must necessarily be submerged in high-pressure helium. Obviously, to sense a possible passage of the gas from the outside to the inside, the leak-detector vacuum system must be connected to the internal volume of the repeater. For this and other reasons, a small-diameter tube that by-passes the seal is provided as a feature of the seal design. After the leak integrity of the repeater is established by this means for all but the access tube, this tube is then used as a means of vacuum drying the repeater and then filling it with extremely dry nitrogen. Following this, the tube is closed by welding and brazing. This closure is then the only remaining leak possibility and is checked by a radioisotope-leak test.

Radioisotope-Leak Test

Of various methods of detecting the passage of very small amounts of a liquid or a gas from the outside to the inside of a sealed repeater, a scheme using a gamma-emitting radioisotope appeared to be the most applicable.

The relatively small region of the welded tube referred to previously, is surrounded by a solution of a soluble salt of cesium-134. With the entire repeater in a pressure tank, hydraulic pressure in excess of service pressures is applied for about 60 hr. The repeater is removed from the tank, the radioactive solution is removed, and the test region is washed by a special process so as to be essentially free from external radioactivity. A special geiger counter is applied to the region. If there has been no leak, the gamma radiation reads a low value. If an intake has occurred of as much as one milligram of the isotope solution, the radiation count is about four to five times greater than that of the no-leak condition. The rate of leak indicated is an acceptable measure of the soundness of the repeater closure.

The helium and subsequent isotope-leak tests are made on a repeater when its glass seals are installed and are performed again on each rubber seal after it is brazed in place.

Electrical Tests

Prior to assembly into the repeater, the various networks are tested under conditions simulating as nearly as is feasible the actual operating conditions of the particular network. The input and output coupling networks and the beta networks enter directly into the insertion gain and hence are held to very close limits. To insure meeting these limits, elements which go into a particular network are

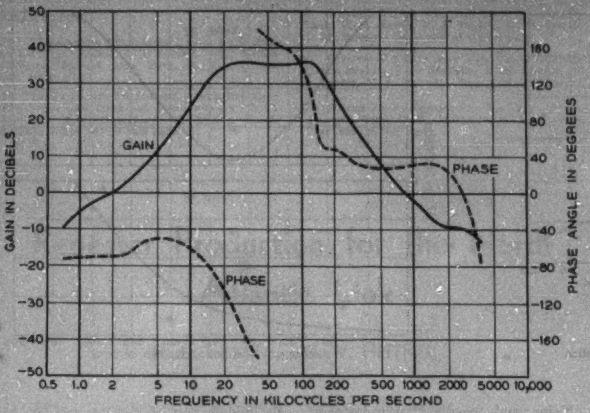

Fig. 18. Mu-Beta gain and phase

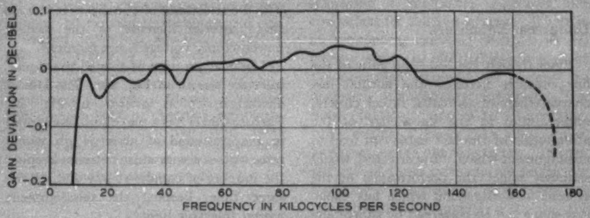

Fig. 19. Repeater deviation from 36.9 NM design cable

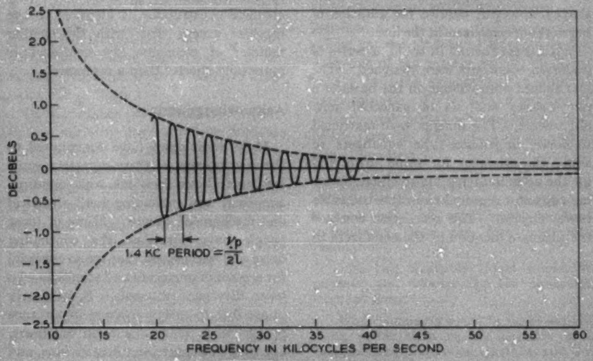

Fig. 20. Interaction ripple for TAC system

matched and adjusted as a group, before assembly into the network.

Repeater units are tested for transmission performance both before and after closing. These tests consist of: Mu-Beta measurements (simultaneous measurements of gain and phase of the feedback loop, noise, modulation, insertion gain at many frequencies, and exact frequency of the fault-location crystal and crystal-peak gain). Modulation and crystal-frequency measurements are made with the repeater energized at 225-ma cable current and also at 245 ma as a check on the ultimate performance of the whole system, initially and after aging.

Performance of Repeaters

The phase and gain characteristics of the feedback loop of the repeater are shown in Fig. 18. It will be noted that, at the upper edge of the band, the feedback is a little less than the 33- to 34-db set as the objective. Additional elements could have been used in the interstages to increase the feedback, but the return per element is small. Since any element is a potential hazard, the lower feedback is acceptable.

The deviation of the insertion gain of the repeater from the loss of 36.9 nautical miles of design cable at sea bottom is shown in Fig. 19. This is well within the objective of ±0.05 db.

It has been pointed out that the repeater input and output impedance do not match the cable impedance. This results in ripples in the system frequency characteristic due to reflections at the repeater. These are shown in Fig. 20.

The noise performance of the repeater is determined by the input tube and the voltage ratio of the input coupling network. Amplifier noise referred to the input is shown in Fig. 21. At the upper frequencies, the repeater contribution to cable noise is very small. At the lower frequencies, while the repeater noise is considerably greater than thermal noise, this does not degrade performance because of the lower cable attenuation at these frequencies.

Manufacturing Drawings

Because of the extraordinary nature of many of the manufacturing problems associated with undersea repeaters, it was determined at the outset that a so-called singled-drawing system would be used. For this reason, considerably more information is supplied than is normal. The effect is illustrated best in the rather large number of drawings that consist of text material outlining in detail a specific manufacturing technique. Such drawings specify the devices, supplies, and work materials needed to perform an operation, and the step-by-step procedure. Of course, these papers are by no means a substitute for manufacturing skill. Primarily, they insure the continuance of practices proved to be effective with the Havana–Key West project.

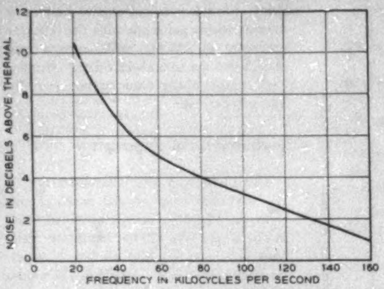

Fig. 21 (above). Repeater noise

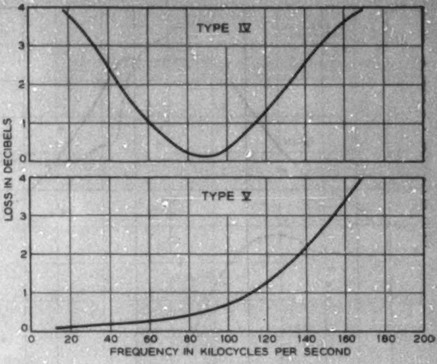

Fig. 23 (right). Equalizer loss characteristics

Repair Repeater

The repair repeater, used to offset the attenuation of the excess cable which must be added in making a repair, is basically the same general design as the line repeater. It employs a 2-stage amplifier, designed to match the loss of 5.3 nautical miles of cable to within ±0.25 db. The larger deviation, compared to the line repeater, is permissible since few repair repeaters are expected to be added in a cable. The input and output impedances match the cable. As in regular repeaters, a crystal and gas tube are provided for maintenance testing. The crystals give approximately 25-db increase in gain and are placed between 173.5 and 174.1 kc, so as not to duplicate any frequencies used in the line repeaters. The crystal-frequency spacing is 100 cycles.

Wherever possible, the same components and mechanical details are used in the repair repeaters as in the line repeaters. When changes in design were necessary, these were modifications in the existing designs rather than new types. Capacitors are like those of line repeaters. Except for the length of the container, the enclosure is identical to the line repeater.

Noise and overload considerations restrict the location of a repair repeater to the middle third of a repeater section.

Undersea Equalizers

Even though the insertion gain of the line repeater matches the normal loss characteristic of the cable rather closely, uncertainties in the knowledge of the attenuation of the laid cable can lead to misalignment which, if uncorrected, would seriously affect the performance of the system. Misalignment which has cable-loss shape can be corrected by shortening or lengthening the cable between repeaters, at intervals, as the cable is laid. Other shapes, however, require the addition of networks or equalizers in the line.

With these factors in mind, a series of undersea equalizers were designed. The loss shapes were chosen on the basis of a power-series analysis of expected misalignments. The designs were restricted to series impedance-type equalizers to avoid the necessity for shunt arms and for the accompanying high-voltage blocking capacitor required to isolate the cable power circuits. This restriction confines the ultimate location of the equalizers to the middle part of repeater sections to minimize the reaction of the poor repeater impedance on the equalizer characteristic. The d-c resistance of equalizers is low, so that material increase of the system power-supply voltage is not required.

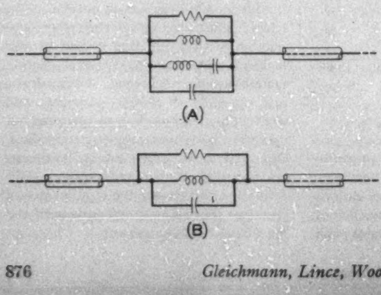

Fig. 22. A—Schematic of type-IV equalizer. B—Schematic of type-V equalizer

The configuration of two of the equalizers are shown in Fig. 22. The loss of characteristics is shown in Fig. 23. Each equalizer has a maximum loss spread in the passband of about 4 db which represents a compromise between keeping the number of equalizers low and, at the same time, keeping the misalignment within tolerable limits.

The components used are modifications of the repeater components. The mechanical construction is identical to the repeater except that, with the smaller number of elements, the container is materially shorter than a repeater.

Acknowledgments

Many individuals have contributed to the development of these repeaters, some leading to basic decisions, some creating, adapting, and perfecting both electrical and mechanical designs. Many of these people have furnished the continuing drive and enthusiasm that are so essential for a team of engineers and scientists who have divergent interests. It is nearly impossible to assign relative importance to the work of transmission engineers, apparatus designers, mathematicians, and research scientists in the fields of materials and processes. Equally difficult is any realistic appraisal of the work of all of the technical aides and shop personnel whose contributions are so significant to the final product. The authors therefore acknowledge this large volume of effort, without listing the many individuals by name.

Repeater Production for the North Atlantic Link

H. A. LAMB W. W. HEFFNER

Synopsis: Production of the submarine telephone cable repeaters, designed to have a minimum trouble-free life of 20 years, required many new and refined manufacturing procedures. Care in the selection and training of personnel, manufacturing environment, inspection, and testing, were of great importance in the successful attainment of the ultimate objective. Although quality of product has always been of major significance in Western Electric Company manufacture, building electronic equipment for use at the bottom of the ocean, where maintenance is impossible and replacement of apparatus extremely expensive, required unusual manufacturing methods.

Manufacturing Objective

LATE in 1952, the manufacture of flexible repeaters for the North Atlantic link of the transatlantic submarine telephone cable system was allocated to the Kearny Works of Western Electric Company.

In accordance with established practice in initiating radically new products and processes, production of these repeaters was assigned to the engineer of manufacture organization rather than to regular manufacture in the telephone apparatus shops. The job was to produce 122 36-channel carrier repeaters and 19 equalizers capable of operating satisfactorily at pressures up to 6,800 psi (pounds per square inch) on the ocean floor, with minimum maintenance, for a period of at least 20 years. Initial delivery of repeaters was required for March 1954, less than a year and a half after the project started.

General Philosophy

Quality has always been the prime consideration in producing apparatus and equipment for the Bell System. There is an economical breaking point, however, beyond which the return does not warrant the abnormal expenditures required to approach theoretical perfection. The same philosophy applies to all manufactured commodities, be they automobiles, airplanes, or telephone systems. In general, all of these products are physically available for preventive and corrective maintenance at nominal cost. In the case of electronic repeaters at the bottom of the ocean, maintenance is impossible and replacement would be extremely expensive.

The general philosophy adopted at the inception of the project was to build integrity into the product to the limit of practicability. To do this, a number of fundamental premises were established, which form the foundation of all operations involved:

1. Manufacturing environment would be provided which, in addition to furnishing a desirable place to work, could be kept scrupulously clean and free from contamination.
2. The best available talent would be screened and selected for the particular work involved.
3. Wage payments would be based on day work, rather than on an incentive plan basis, because production schedules and the complexity of the operations did not permit the high degree of standardization essential to effective wage incentive operation.
4. A sense of individual responsibility would be inculcated in every person on the job.
5. Training programs would be established to thoroughly prepare supervisors, operators, and inspectors for their respective assignments before any work was done on the project.
6. Inspection, on a 100% (per cent) basis, would be established at every point in the process which could, conceivably, contribute to or affect the integrity of the product.

Preparation for Manufacture

Manufacturing Location

It appeared desirable to set up manufacture in a location apart from the general manufacturing area. Experience gained to date has indicated that this was the correct approach, since it provided a number of advantages:

1. Administration has been greatly facilitated by having all necessary levels of supervision located in the immediate vicinity of the work.
2. It was necessary for the people on the job to acquire and maintain a new philosophy of perfection in product, rather than a high output at an "acceptable quality level." This was easier at a separate location, since only one philosophy was followed throughout the plant.
3. Engineering, production control, service, and maintenance organizations were located close to actual production and had no assignments other than the project.
4. The small plant, due to its semi-isolation, tends to produce a very closely knit organization and good teamwork.

A large number of manufacturing locations were examined and the one selected was a 1-story modern structure in Hillside, N. J., which provided a gross area of 43,700 square feet.

The entire plant was air conditioned; in most cases, the temperature was controlled to minimum 73 F (degrees Fahrenheit), maximum 77 F. The air was filtered through two mechanical filters and one electrostatic filter. Relative humidity was maintained at maximum 40% in all but one area, the capacitor-winding room, in which it was necessary to maintain maximum 20% humidity to avoid mechanical difficulty with capacitor paper. While most of the air was recirculated, the air from the cafeteria, cleaning room, locker, and toilet rooms was exhausted to the outside atmosphere. Two separate air-conditioning systems were in use. One, of 300-

ton capacity, provided for most of the plant, while a smaller unit of 30-ton capacity served the capacitor winding, testing, and impregnating rooms. Each installation had its own air filtering and conditioning equipment.

PLANT LAYOUT

The plant layout is illustrated in Fig 1. All working areas, with the exception of the repeater enclosure area, were individually enclosed, and walls from approximately 4 feet above the floor were almost entirely of reinforced glass. This arrangement facilitated supervision by other than first-line supervisors, who were located with the groups, and provided a means of viewing the operations by the many visitors at Hillside, without contaminating the critical areas or disturbing the operators.

ANALYSIS OF DESIGN FOR FACILITIES AND OPERATIONS

In analyzing the design for manufacture there were, of course, numerous instances where conventional methods and facilities were entirely adequate for the job. Since their inclusion would contribute little to this article, the description will be confined to those cases which are new or unusual.

COLLABORATION WITH BELL TELEPHONE LABORATORIES IN PREPARATION OF MANUFACTURING INFORMATION

Early in 1953, a co-ordination committee was established, consisting of representatives from the various Laboratories design groups and Western Electric engineers, which met on a biweekly basis during the entire period preceding initial manufacturing operations. These meetings provided a clearing house for questions and policies of a general nature for this particular project and served to keep all concerned informed as to the progress of design and the preparations for manufacture.

It is customary, during the latter stages of development of any project at the Laboratories, for Western Electric engineers to participate in the preparation of manufacturing information as an aid in pointing the design toward the most economical and satisfactory production methods and facilities. Since the decision to use the Bell System repeater in the transatlantic system was based on the performance of the Key West–Havana installation, and the fact that changes in design would require further trials over an extended period, only minor changes to facilitate manufacture were made. Further, since some experience had been gained by the Laboratories in producing repeaters for that installation, it was decided to pool effort in preparing the manufacturing process information, which is normally Western Electric's responsibility. Close co-operation of the two groups therefore has resulted in the production of repeaters which are essentially replicas of those in the initial installation except for the internal changes necessary to increase transmission capacity from 24 to 36 channels.

OTHER WESTERN ELECTRIC LOCATIONS AND OUTSIDE SUPPLIERS

During the development work on the Key West–Havana repeaters, the Hawthorne Works of Western Electric had furnished the molybdenum-permalloy cores for certain inductors, the Tonawanda Plant had furnished mandrelated resistance wire, and the Allentown Plant had fabricated the glass seal subassemblies. Since the experience gained in this development work was extremely valuable in producing the additional material required for the transatlantic system and since the facilities for doing the work were largely available, these various locations were asked to furnish similar material for the project. Although the Kearny Crystal Shop had not been involved in the Key West–Havana project, arrangements were made to make the crystals there for this project, since facilities were available, and because of a considerable amount of experience in producing precision units.

SUBCONTRACTED OPERATIONS

While it was believed, initially, that all component parts for repeaters should be manufactured by Western Electric, critical analysis indicated that it was neither desirable nor economical in certain cases. One of the outstanding examples in this category is the hardened and ground chrome-molybdenum steel rings that constitute the strength members in the repeater and sustain the pressures developed on the ocean bottom. Purchasing the many large and varied machine tools and associated heat-treating equipment necessary to produce these parts would have required a substantial capital expenditure and additional manufacturing space. Arrangements were therefore made with a highly qualified and well-equipped supplier to produce the rings, of material furnished by Western Electric, which had been previously inspected and tested to very stringent requirements.

The situation attending the manufacture of a relatively small number of comparatively large copper parts used in the rubber and core tube seals was much the same. Here, again, the large-size machine tools and additional manufacturing space, required for only a short time, would have increased the over-all cost of the project considerably. These parts therefore were subcontracted in the local area and inspection was performed by Hillside inspectors.

A safeguard, in so far as integrity is concerned, was provided by the fact that these were individual parts that could be reinspected at the time of delivery. No subassembly operations that might possibly result in oversight of a defect, were subcontracted.

MANUFACTURING CONDITIONS

Two major problems confronted us in planning the manufacture of repeaters; first, to produce units that were essentially perfect and, second, to prevent the contamination of the product by any substance that might degrade its performance over a long period. In approaching both of these objectives, it was realized that the product had a definite economic value which the cost of production should not exceed. Therefore in many cases it was necessary to rely on judgment, backed by considerable manufacturing experience, in determining when the "point of no return" had been reached in refining processes and practices.

The initial approach to this phase of the job was to classify, with the collaboration of Bell Telephone Laboratories, all of the manufacturing operations involved as to the degree of cleanliness required. In setting up these criteria, it was necessary to evaluate the importance of contamination in each area and the practicability of eliminating it at the source, or to ensure that whatever foreign material might accumulate on the product would be removed.

A representative case is the machining of piece parts. While the shop area is cleaner, perhaps, than any similar area in industry, the very nature of the work is such that immediate contamination cannot be avoided, since material is being removed in the form of chips and turnings, and a water-soluble oil is used as a coolant. In this instance, however, the parts can be thoroughly cleaned and their condition observed before leaving the area. Conversely, in the case of an operation such as the assembly of paper capacitors in a container which is then hermetically sealed, it is vitally necessary to ensure that both the manufacturing area and the processes are free from, and not conducive to producing, particles of material which are capable of causing trouble.

The various classifications established for the production areas include specific requirements as to temperature, relative humidity, static pressure with respect to adjacent areas, cleanliness in terms of restrictions on smoking and the use of cosmetics and food, and the type and use of special clothing.

SPECIAL CLOTHING

Employees' clothing was considered one of the most important sources of contamination for two reasons; first, because of the foreign material that could be collected upon it and carried into the manufacturing areas and, second, because various types of textiles in popular use are subject to considerable raveling and fraying.

After considerable study of many types of clothing for use in critical areas, the material adopted was closely woven Orlon, which has proved to be acceptably lint-free. The complete uniform, supplied at no cost to the employees, consists of slacks and shirts for both male and female employees, Orlon surgeon's caps for the men and nylon-visored caps for the women. In addition, shoes, without toecap seams, were provided. Nylon smocks were furnished to protect the uniforms while employees moved from locker rooms to the entrance vestibule. Two changes of clothing were provided each week, and the laundering was done by an outside concern.

Employees to whom this special clothing was issued were paired for locker use. Each pair kept their uniforms and special shoes in one locker and their own clothes and shoes in the other. This prevented the transfer to the uniforms of any foreign material that might exist on the street clothing. At the entrance vestibule to the *A*, *B*, and *C* areas, Fig. 1, the employees were required to clean their shoes in the specially designed facilities provided and to wash their hands in the wash basins installed for this purpose. Smocks were then removed and hung on numbered hooks that line the walls at the end of the vestibule. Employees were then permitted to go to their work positions within the inner areas. At any time that it was necessary for employees to leave the work areas for any purpose, they were required to put on their smocks in the vestibule and upon their return, to go through the cleaning procedure again.

Employees in the other areas were provided only with smocks, mainly for the protection of their clothes, since the work involved could soil or stain them, but could not be contaminated from the clothing.

CLEANING

Schedules were established for cleaning the areas at regular intervals, the frequency and methods depending upon the type of manufacturing operations and the activity. Usually, the vinyl plastic floors were machine-scrubbed and vacuum-dried. Walls, windows, and ceilings were cleaned by hand with lint-free cloths. Manufacturing facilities such as bench tops, which were linoleum-covered, were washed daily. Test sets, cabinets, test chambers, and bench fixtures were also cleaned daily. Hand tools were cleaned at least once a week by scrubbing with a solution of green soap, rinsing in distilled water followed by alcohol, and then dried in an oven.

DUST COUNT

Since it was impossible to determine what contaminating material in the form of air-borne particles might be encountered from day to day, and what the effect might be during the life of the repeaters, the general approach to this problem was to control, so far as possible, the amount of dust within the plant.

To verify, continuously, the over-all effectiveness of the various preventive measures, dust counts were made in each classified area at daily intervals, using a Bausch and Lomb dust counter. This device combines, in one instrument, air-sampling means and a particle-counting microscope. Over a 2-year period, it has been possible to maintain, in certain areas, a maximum dust count of between 2,000 and 3,500 particles per cubic foot of air with a maximum size of 10 microns. Control checks, taken outside the building at the employees' entrance, generally run upward of 25,000 particles per cubic foot, a good portion of which are of comparatively large size.

Production and Personnel

Equipping the plant, obtaining and installing facilities, and selecting and training personnel proceeded on a basis of close overlapping, with receipt and analysis of Bell Telephone Laboratories' product design information. Because of the critical nature of the product, provisions were made not only for the most reliable commercially available utilities and services but also for emergency lighting service in some areas. It was necessary for maintenance and service staffs to be built up rapidly at the same time that the supervisory and manufacturing forces were being developed.

QUALIFICATION OF ALL PERSONNEL

Before employees were assigned to production work there were required to pass a qualification test established by the inspection organization to demonstrate satisfactory performance. Programs were therefore set up for "vestibule" training and qualification of new employees. This activity was carried on by full-time instructors who had been trained by Western Electric and Bell Laboratories engineers. Training was carried out in two stages:

1. (a) The employee received instruction and became acquainted with equipment and requirements. (b) A practice period was established in which the employee developed techniques and worked under actual operating conditions, with all work submitted to regular inspection.

2. During a qualification period, the employee was required to demonstrate that work satisfactory for project use could be produced.

The main objective during stage 1 was progressive quality improvement, and in stage 2 the maintenance of a satisfactory quality level over an extended period. Employees made a definite number of units at acceptable quality levels in order to qualify. The number of units required for training varied with the type of work and the ease with which it was mastered.

All personnel were required to pass qualification tests before being assigned to production work and were restricted to that work unless trained and qualified for other work. Employees trained on more than one job were requalified before being returned to a previous assignment.

Records of the performance of individual operators started in the training stage were continued after the employees were assigned to production work. The performance record of the operators was based on results obtained during the inspection of their work, while that of the inspectors was based on special-quality accuracy checks of their work.

PERSONNEL SELECTION

It was apparent that the new manufacturing techniques, including the cleanliness and quality demands, would necessitate that all shop supervisors and employees be very carefully selected. It also appeared (and this was subsequently confirmed) that after the careful selection and training of supervisors, long training periods would be required for specially selected shop employees.

In selecting first-line shop supervisors, such factors as adaptability, personality, and ability to work closely with the engineers were of paramount importance. For the parts and apparatus included in their responsibility, they were required to learn thoroughly the design, the operations to be performed, the facilities to be used, the data to be recorded, the cleanliness practices to be observed—and, in most cases, prepare themselves to be able to perform practically all of the operations, because subsequently they would train selected operators to perform critical operations to very high-quality standards under rigidly controlled manufacturing conditions. As shop supervisors and employees were assigned to the manufacture of repeaters, they were thoroughly indoctrinated in the design intent and the new philosophy of manufacture.

Standard ability and adaptability tests were used in a large number of cases to assist in proper selection and placement of technicians: tests for finger and hand dexterity; for sustained attention; eye tests, including perception and observation; and tests for reaction time of the right foot after a visual stimulus. (The latter test was relatively important for induction-brazing operations.) Other requisite considerations were a high degree of a dependability and integrity, involving intellectual honesty and conscientious convictions; capability of performing tedious, frustrating, and exasperating operations against ultrahigh-quality standards, verifying their own work; perseverance and capability to adapt easily to changes in assignment and occupation or the introduction of design changes. We considered whether or not the employees would stand up under "fishbowl" operations, wherein they would receive a considerable amount of observation from high levels of Western Electric Company and Bell System management, and other visitors. Also, could they duplicate high quality frequently after qualifying for a particular operation?

During the period of repeater manufacture, the number of employees rose from less than 50, in January 1954, to a maximum of 304 by February 1955, after which there was a gradual reduction to a level of about 265 employees for 6 months and then a gradual falling off as we were completing the last of the project. In the period from May to December 1954, between 30 and 45 employees were constantly in training prior to being placed on productive work. During 1955, this decreased to practically no employees in training during the mid-part of the year and thereafter training was required merely to compensate for a small labor turnover and employee reassignment. It is significant that labor turnover was very low and attendance was exceptionally good during the life of the Hillside operations.

PERSONNEL TRAINING

The original plan, which was generally followed, was to prove in the tools for each phase of the job, followed by an intensive program of training. Indoctrination of laboratory technicians could be considered as "vestibule training" in that they were acclimated to the area and conditions, given oral instruction in the work, then given practice materials and demonstrations and, when qualified, were started on making project material. To do this, extra supervisors were required at the beginning of the job. A supervisor trained a few employees, qualified some of them, and began work on the project. Another supervisor was then required to train additional employees who, as they became qualified, were transferred to the supervisor responsible for making project apparatus. Additional testing of the employees, instruction and reinstruction and, in some cases, retraining were required. In practically all cases, we were able to fit an employee selected for work at Hillside into some particular group of operations. The extra emphasis on selection and training created a well-balanced team that later resulted in considerable flexibility. During all of this training our supervisors worked closely with engineers and inspectors who understood the design intent and the degree of perfection required.

At the beginning, each technician was trained for only one operation of a particular job, such as: 1. winding type-X capacitors, 2. impregnating all paper capacitors, or 3. winding type-Y transformers, and so became an expert on this one operation. Later, the tours of duty for many technicians were broadened to cover several operations.

COMMUNICATIONS

To keep employees informed, the entire group was occasionally assembled, and informative talks were presented on current production plans and future business prospects. Motion pictures were shown of the cable-laying ships and the operations of cable splicing and cable laying. A display board, showing all of the repeater components, was mounted on the wall of the cafeteria. This informed the operators exactly where the parts were used in apparatus; also where their products went into the wired repeater unit, and how all electric apparatus was enclosed against sea pressure in the final repeater. In small groups, all of the employees at Hillside were given a short guided tour of the plant to see the facilities and hear a description of the operations being performed in each area. These communications were extended to everyone at the Hillside Plant, including those who did not work directly on the product. It was our conviction that the maintenance men, boiler operators, oilers, station wagon chauffeur, janitors, and clerical workers in the office were all interested and could do a better job if kept informed of the needs and progress of the project.

SCHEDULING

Capacity was provided at the Hillside Shop to manufacture a maximum of 14 repeaters in a calendar month. This envisioned 6-day operation with some second-shift and third-shift operations; due allowance was made for holidays and vacations, so that the annual rate would be approximately 160 enclosures per year. (An enclosure is either a repeater or an equalizer.)

Some of the facilities and raw materials were ordered late in 1953. This ordering expanded early in 1954 and continued through 1955 to include parts to be made by outside suppliers and the parts and apparatus to be made at Hillside. Apparatus designs were not all available at the beginning of the job, and the ultimate quantities required were also subject to sharp change as the project developed, thus further complicating the scheduling problem.

Because of the time and economic factors involved, coupled with the developmental nature of the product and processes, one of the most difficult and continuing problems was the balancing of production to meet schedules. For this task, "tree charts" were devised for the apparatus codes and time intervals in each type of repeater or equalizer for each project. Each chart was established from estimates of the time required to accomplish the specified operations and the percentage of good product each major group of operations was expected to produce.

Raw Materials

Many of the specifications were written around the specific needs of the job and embodied requirements that were considerably more stringent than those imposed on similar materials for commercial use. As a result, it was necessary for many suppliers to refine their processes and, in some cases, to produce the material on a laboratory basis.

One example is the container, or repeater enclosure, which consists, in part, of a seamless copper tube approximately $1^{3}/_{4}$ inches in diameter having a 1/32-inch wall and which is approximately 8 feet long. This material was purchased in standard lengths of 10 feet. The basic material was required to be phosphorus deoxidized copper of 99.80% purity. The tubing, as delivered, had to be smooth, bright, and free from dirt, grease, oxides (or other inclusions including copper chips), scale, voids, laps, and slivers. Dents, pits, scratches, and other mechanical defects could not be greater than 0.003 inch in depth. The tubing had to be concentric within 0.002 inch and the curvature in a 10-foot length could not exceed $^{1}/_{2}$ inch, to facilitate assembly over the steel rings.

Only one supplier was willing to accept orders for the tubes, and only on the basis of meeting the mechanical requirements on the outside surface. To establish a source of supply, it was necessary to accept the supplier's proposal on the basis that some of the tubes produced could be expected to meet requirements on the inside as well as the outside surface. Inspection of the inside surface was performed with a 10-foot borescope.

The supplier then set aside, overhauled, and cleaned a complete group of drawing facilities for this project. In addition, a number of refinements were made in lubrication and systematic maintenance of tools. After all refinements were made and precautions taken, however, the yield of good tubes in the first 400 produced was less than 1.0%. Consultations with Western and Bell Laboratories' engineers, and the supplier's cooperation, raised the yield to approximately 50%.

Procurement of satisfactory mica laminations for capacitors introduced an unusual problem. The best grade of mica available in the world market was purchased, which the supplier, under special plant conditions, split and processed into laminations. Despite care in selection and processing, only 50% of the 250,000 laminations purchased met the extremely rigid requirements for microscopic inclusions and delaminations, and less than 8% survived the capacitor manufacturing processes.

A large number of the parts, and the most complex, are made from methyl-methacrylate (Plexiglass). At the time manufacture began, there was little, if any, experience or information available on machining this material to the required close tolerances and surface finish. Consequently, considerable pioneering effort was expended in this field before satisfactory results were obtained.

The methacrylate parts cover a wide range of size and complexity, from tubular housing $1^{1}/_{8}$ inches in diameter and $4^{7}/_{8}$ inches long to tiny spools 1/8 inch in diameter and 1/16 inch long. Most of the parts are cylindrical in shape with some semicylindrical sections that must mate with other sections to form complete cylinders. Others have thin fins, walls, flanges, and projections. Five representative parts are shown in Fig. 2.

Methyl-methacrylate has a tendency to chip if tools are not kept sharp and if care is not used in entry or exit of the tool in the work, particularly in milling. In some cases it is necessary, with end milling, to work the cutter around the periphery of the area for a slight depth so that subsequent cuts will not break out at an unsupported area. Normally, with a sharp cutter and a 0.010-inch finish cut, and a slow feed, chipping will not result. High-speed steel tools with zero rake were used for turning and boring operations. Standard high-speed milling cutters and end mills were used for milling except for the cutting edges, which are honed to a fine finish. A clearance angle of 7 degrees for milling and 10 to 15 degrees for lathe work was found most satisfactory. In lathe work, the general rule was light feeds (0.003 to 0.005 inch) and small depth of cut. However, the depth of cut could be safely varied over a wide range, depending upon many factors, such as type of part, quality of finish, machine and tool rigidity, effective application of coolant, and tooling to support and clamp the part. In one operation of boring a blind hole, $1^{3}/_{16}$ inches in diameter and $4^{1}/_{8}$ inches deep, within ±0.002 inch, the boring terminates in simultaneously facing the bottom of the hole square with its axis. A cut 19/32 inch deep with a light feed was taken with a specially designed boring tool and with the coolant being fed through the shank to the cutting edge. All completely machined parts were annealed for 12 hours at 175 F.

Highlights in Assembly and Brazing

Repeater units are encased in hardened steel rings which previously had been tested at 10,000-psi hydraulic pressure. This pressure is approximately 50% higher than the greatest pressure expected at ocean bottom. The steel rings were encased in a copper sheath and closed at each end with a glass-to-Kovar seal, with the central conductor coming through the glass to the outside. The copper sheath was then shrunk to the steel rings and glass seals using 6,000-psi hydraulic pressure, and the glass seal was then high-frequency brazed to the copper sheath.

To keep the ocean bottom pressure off the glass seals and also to terminate the cable insulation, a rubber seal is brazed in to the copper container tube adjacent to each glass seal. This rubber seal consists of rubber bonded to brass, which has been brazed to the copper portion of the seal. The rubber terminates in polyethylene through five steps of compounds containing successively less rubber and more polyethylene. The polyethylene can be readily bonded by molding to the polyethylene insulation of the cable. The central conductor passes through a central brass tube in the rubber seal, which is also bonded to the rubber.

To protect the rubber seals from the deleterious effects of salt-water immersion for long periods, a copper-core tube is brazed over each rubber seal. The core is arranged to equalize the pressure inside and out when submerged at ocean bottom pressure. This is accomplished with a bulge of neoprene filled with polyisobutylene, on the far end of the core tube, which transmits the pressure to the inside of the core tube seal.

To make doubly sure that no salt water reaches the rubber seal, a copper cover is brazed into the container outside the core tube connector on each end. This cover is also brazed to the core tube connector. The interstice between each of these four seals is filled with polyisobutylene, which is viscous and inert and has very good insulating qualities.

Each end of the repeater closure, Fig. 3, contains five successive brazed joints. Any one of these ten brazes, if not perfect, could cause the loss of the repeater closure and jeopardize the entire repeater. All of these brazes were made with the repeater in a vertical position to ensure an even distribution of the brazing alloy fillet around the joint.

An up-ending device was provided at the pit-brazing location to raise to repeater on its carrier to a vertical position with either end up, and move it into position for brazing. The repeaters were brought into the brazing area on an overhead monorail and an electric hoist. The shorter repeater assemblies, before core tube and cable stub assembly, were up-ended by hand and brazed from a raised platform.

It was necessary to make all of these brazes by high-frequency induction heating, since the heat must be very intense, contained within a very narrow band, evenly distributed, and the area protected from oxidation by a somewhat reducing atmosphere. The heat had to be very intense since the time interval for the shortest braze was 10 seconds maximum and the longest 30 seconds. A large part of the heat was dissipated by being conducted at a high rate from the copper parts to the water in the cooling jackets used to contain the heat in a very narrow band.

Circulating cooling water within a jacket prevented heat from being conducted down the copper container tube to the preceding seals or to the repeater unit. This water-cooled jacket was positioned only 3/8 inch below the inductor, and the water was in intimate contact with the container tube, which is sealed off at both ends with rubber O-rings. In addition, for the glass seal braze, the glass inside the seal cavity was kept covered with water during the heat cycle. The water was fed in and siphoned out to a constant level which was kept under observation by the operator and the inspector to make sure that the glass was covered at all times. The rubber seal was also water-jacketed on the inside of the seal to prevent deleterious effects of the heat on the rubber insulation around the central conductor. The inner cover braze was quenched before the 10-second maximum interval had expired to ensure that the heat did not penetrate to the polyisobutylene at a sufficient rate to deteriorate it or the rubber inside.

Distribution of the heat around the container tube at the braze area was controlled by locating the work in the inductor so that the color came up essentially evenly all the way around and at the proper level to bring a fillet up to the top of the braze joint within the allowable time limit. The time limit was determined by experiment so that none of the previously assembled parts were damaged by the heat. This determination of the proper heat pattern and the prevention of overheating required the development of considerable skill on the part of the operator. The variables encountered made it essential to rely on an operator to control the heat rather than to utilize the timer with which the induction heating equipment is normally controlled.

The area to be heated for brazing was protected from oxidation by enclosing it in a separable transparent plastic box and flooding the interior with a gas consisting of 15% hydrogen and 85% nitrogen. This atmosphere is somewhat reducing and not explosive. The brazing surfaces of the parts were chemically cleaned immediately before assembly and extreme care was exercised to keep them clean until brazed.

The container tube was shrunk to the respective glass, rubber, core tube, and cover seals with the use of hydraulic pressure so that the surfaces to be brazed and the brazing alloy were in intimate contact within the brazing area. If the parts were clean and kept from oxidizing by the protective atmosphere, the alloy would flow upward by capillary action and form a fillet around the top of the seal, impervious to any leak.

The braze in each case was then leak-tested with a helium mass-spectrometer type of leak detector. A gas pressure of helium at least 25% greater than the maximum pressure to be encountered at ocean bottom was used. In addition, a radioisotope was used to test the effectiveness of the final tubulation pinch welds and overbrazes which were kept open for the leak tests under high-pressure helium. These tests were made with water pressure about 25% greater than the maximum ocean bottom pressure.

The completed repeater was inserted in a chamber 80 feet long; the chamber was then filled with water and the pressure raised to 7,500 psi and held at that pressure for at least 15 hours. At the end of this period the closure had to show no sign of crushing or leaking.

The repeater unit sealed in the closure must be extremely dry to function properly. Any water vapor which might remain after the closure is sealed, or enter during the estimated 20-year minimum life, must be scavenged. A sealed desiccator with a thin diaphragm was therefore assembled into the repeater unit sections. After completely drying and sealing the repeater unit except for one tubulation, the diaphragm of the desiccator was ruptured by dry nitrogen pressure and, with the enclosure filled with dry nitrogen, the final tubulation was immediately sealed off. To ensure that the diaphragm was actually broken, a microphone was strapped to the outside of the repeater over the location of the desiccator and a second microphone arranged at the end of the closure to pick up background noises. A pen recorder was used to record the sound from the two microphones and also the change in nitrogen pressure. Three simultaneous pips on the chart gave definite indication that the diaphragm had ruptured and that the desiccant had been exposed to the internal atmosphere of the repeater.

Quartz Crystal Units Manufactured at Kearny

The primary purpose of the crystal unit is to provide the means of identifying and measuring the gain of each repeater in the cable. This basic crystal design is in common usage. The exacting specifications for this application, however, imposed many problems and deviations from normal crystal-manufacturing processes.

Raw quartz was specially selected for this crystal unit. The manufacturing process of reducing the quartz to the final plate followed the recognized methods through the roughing operations. Because of the rigid end requirements, the finishing operations were performed under laboratory conditions. Angular tolerances were one third of normal limits. No evidence of surface scratches, chipped edges, or other surface imperfections visible under 30× magnification were permitted. This resulted in a process shrinkage five times that experienced in normal crystal plate manufacture.

In this use, the crystal units were required to meet performance tests at currents as low as 1/1,000 microampere, far below the current values usually encountered. Improved soldering techniques had to be developed for soldering the gold-plated phosphor bronze and nickel wires used, because it was found that the electrical performance of the units was directly related to the quality of soldered connections.

Although one seventh of Western Electric's production of quartz crystal units are in glass enclosures, the applicable techniques in glass working required a complete revision. Glass components such as the stem and bulb purchased from established sources were found to be far below the standard required for this crystal unit. For example, the supplier of the glass tubing used in the manufacture of stems was required to meet raw material specifications that embodied coefficient of thermal expansion, softening point of glass, density, refractive index, and volume resistivity. The glass stems made from this tubing by regular manufacturers were found unacceptable and the processes used by these sources could not be readily adapted to meet the desired specifications. The glass stems contained four lead wires made from 30-mil grade *A* nickel wire butt welded to 16-mil light borated Dumet wire. To assure the quality of the metal to glass seal, each wire was inspected under 30× magnification for tool marks and other surface imperfections. The finished stem assemblies were inspected under 30× magnification for dimensions, workmanship, cleanliness, and minute glass imperfections, then individually stored in a sealed plastic envelope.

The glass bulb in this crystal unit is known as the *T921* design commonly used in the electron tube industry. The high quality required, however, made 100% inspection necessary. Examination under 30× magnification resulted in rejected bulbs for presence of scratches, open bubbles, chips, and stones. Physical limits for inside and outside diameters as well as wall thickness were causes for additional rejects. Only 1% of the commercial bulbs were found acceptable, and these were all stored in a sealed plastic envelope.

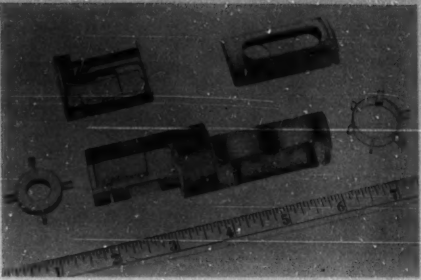

Fig. 2. Methyl methacrylate parts

The final major assembly operation consisted of sealing the glass bulb to the stem which had had the crystal subassembly welded to the nickel wires. The techniques for "sealing in" used in quartz crystal or electron tube manufacture were unsuited. Two important factors in this crystal unit, which required the development of new processes, were the proximity of soft-soldered connections to the sealing fires and the demands that the glass seal contain a minimum of residual tensile stress. These two problems were resolved collectively by performing the sealing operation on a single-spindle glass-sealing machine. Accurate positioning of the glassware and sealing fires, together with precise timing and temperature controls, achieved the desired results.

Evaluation of residual stresses were made by inspections with the use of a polarimeter, and by a thermal shock test. The maximum safe stress was established at 1.74 kilograms per square millimeter. The thermal shock test required successive immersion of the unit in boiling water and ice water. The electrical characteristics of these units exceeded all others made previously by Western Electric. The ratio of reactance to effective resistance Q was greater than 175,000, twice that ever previously produced and 17 times that required in the average filter crystal.

Stability for frequency and resistance was assured by a 28-day aging test. During this period, precise daily resonant frequency and resistance measurements were recorded against temperature within 0.1 degree centigrade. The maximum permissible change was 0.0005% in frequency and +5% to −10% in resistance.

Glass Seals Manufactured at Allentown

The glass seal used to close each end of the container for the repeaters and equalizers is manufactured at the Allentown Works of the Western Electric Company.

The unit is essentially a glass-bead-type seal. It insulates the central conductor of the repeater from the container and serves as a final vapor barrier between the cable and the interior of the repeater. As such, it backs up several other rubber and plastic barriers as shown in Fig. 3.

Fig. 4 shows the various components, subassemblies, and a cross section of the unit. The unit consists of the basic seal brazed in the Kovar outer shell, to which is brazed a copper extension provided with two brazing-ring grooves. One of these grooves is used in brazing the seal, along with support members, into a length of container tubing in the same manner as the seal is ultimately brazed into the repeater. Packaging of the seal in this manner was necessary to pressure test the seal. Under test, in a specially constructed chamber 10,000 psi of helium gas pressure was applied to the external areas of the packaged glass seal and a mass spectrometer-type leak detector was connected through the tubulation to the internal cavity of the packaged unit. In this manner, the interface of the glass to metal seal, the brazed joints, and the porosity of the metal were checked for leakage. The unit is left in this package for delivery to provide protection during shipment. Before the seal could be used, it was machined from the package by cut-

ting the copper extension to length leaving the second groove for use in brazing the seal to the repeater and removing the container tubing and support members.

The basic seal consists of the cup, central conductor, and glass. The cup (the smaller cylindrical item in the upper left-hand corner of Fig. 4) was machined from Kovar rod. The wall of the cup is tapered from a thickness of 0.025 inch at the base to 0.002 inch at the lip. The last 0.006 inch of the lip is further tapered from this 0.002 inch to a razor edge. The internal surface is better than a 63-micro-inch turned finish and was also liquid-honed to give it a uniform matte finish. The central conductor (the slim piece in the upper right-hand corner of Fig. 4) was also machined from Kovar rod. Both the cup and central conductor were further processed by pickling, hypersonically cleaning in deionized water, and decarburizing. The glass, a borosilicate type of optical quality, was cut from heavy-walled tubing. The glass tubing was hand-polished, lapped, and etched to remove surface scratches, and to arrive at the specified weight. It was also fire-polished and hypersonically cleaned to remove all traces of surface imperfections and to assure maximum cleanliness.

To make the basic glass seal, the metal parts had to be oxidized under precisely controlled conditions. For the oxidizing operation, a suitable fixture was loaded with brazed shell-cup assemblies, central conductor assemblies, and a Kovar disk, which had been prepared in precisely the same manner as the cups and central conductors. The disk was carefully weighed before and after oxidizing and the increase in weight divided by the area involved yielded the weight gain due to oxidation for each run. Limits of 1.5 to 2.5 milligrams per square inch of oxide were set. This operation was performed by placing the loaded, sealed retort, through which passed a metered flow of dried air, into a furnace for a specified time-temperature cycle.

In the glassing operation the oxidized shell assembly, the carbon mold, and the central conductor were placed in a fixture and held in the proper relationship. The carbon mold served to support the glass while it was being melted, in that section between the cup and central conductor where the glass was normally unsupported. The prepared cut-glass tubing was loaded into the Kovar cup and the fixture was sealed into the retort. During the glassing cycle, a constant flow of nitrogen passed through the retort to provide an atmosphere which minimized any reduction or further oxidation of the already carefully oxidized parts. After the proper purging period, the retort was placed in the furnace. In the furnace, the glass melted and formed a bond with the oxidized Kovar of the cup and central conductor to form the seal. After the specified temperature-time cycle, the retort was removed from the furnace, allowed to cool partially, and then placed into an annealing oven.

Vertical furnaces and retorts were used for brazing, decarburizing, oxidizing and glassing. By varying the type of gases flowing into the retorts, atmospheres which are reducing, oxidizing, or neutral were obtained. To provide maximum uniformity of process, separate retorts and holding fixtures were provided for operations involving hydrogen and for air-nitrogen operations, so that a retort or a fixture used for hydrogen treatments was never used for oxidizing or glassing.

Pilot and Regular Production

We called our first efforts Practice Parts and Training; the next we called Pilot Production. Next, certain items identified as "trial-laying repeaters and oscillators" were manufactured for use in proving in the ship-laying gear. To prove in manufacturing facilities, a few unequipped housings were made without the usual electrical components normally in a repeater. Similarly, each of the apparatus components and parts required exploratory and pilot effort before regular production could be undertaken.

As might be expected, the manufacturing yield of components meeting all requirements was very low during the early stages of the undertaking. However, substantial improvement was brought about as experience was gained. Comments on some of the production problems, highlights, and yield results, are in the following paragraphs.

PAPER CAPACITORS

Paper capacitors were manufactured only after painstaking qualifying trials and tests had been performed on each individual roll of paper. Cycling and life testing, procurement of acceptable ceramic parts and gold-plated tape and cans, selection and matching of rolls of paper for winding characteristics, and similar problems, all had to be completely resolved to a point of refinement previously unattempted for telephone apparatus.

Composite percentage yield for all operations on paper capacitors is shown in Fig. 5. Yield is shown as the ratio of the finished units of acceptable quality to the number of units started in manufacture.

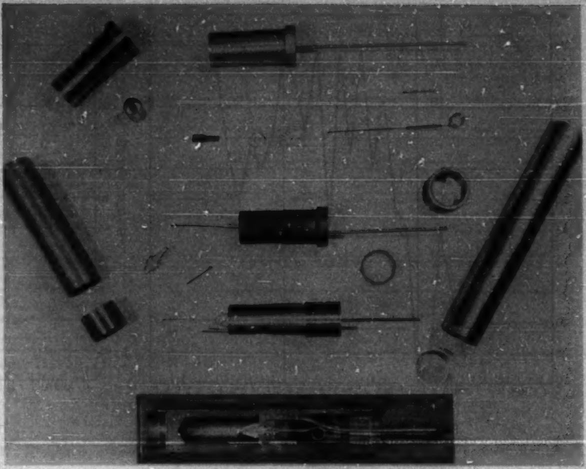

Fig. 4. Glass to Kovar seals

Mica Capacitors

Mica capacitors were made from only the most meticulously selected laminations, as mentioned earlier. Even the best mica is particularly susceptible to damage in processing. In spite of experience and knowledge of this, the multiple handling of the laminations contributed an unusually high material shrinkage as each separate lamination needed to be cleaned, then handled individually many times through the processes. The art of silk screening was applied to deposit silver paste in a specific area or areas on each side of a lamination. A sharply defined rectangular area was required so that when the laminations were superimposed one over another the desired capacitance would be obtained. Cementing of mica laminations onto machined methacrylate forms presented some additional problems through the bowing of the mica laminations as the cement cured. Obtaining screens that would give the proper length and width dimensions for the coated area, was another problem. A silk screen woven of strands of silk obviously limits, by the diameter of the threads, the extent to which the dimensions of an opening may be increased or decreased. Soft copper U-shaped terminals were used to clamp the layers of mica together into a stack. Control of the pressure used in crimping these terminals was found to be very critical in view of the exceptionally tight limits on capacitance and stability. Fig. 6 shows the composite yield at various times for all mica capacitors.

Resistors

There were three designs of ceramic resistors, which were resistance-wire wound on ceramic spools. These were intended to be assembled into the hole inside the core tube on which the paper capacitors were wound. Special winding machines equipped with binocular attachments were necessary to wind these resistors. Other resistors were hand wound on methylmethacrylate forms, or on the outside of the ceramic containers, for certain types of paper capacitors. Rough adjustments were required of the lengths of resistance wire prior to winding, and close adjustments to resistance values were made after the windings were completed and before leads were attached to resistors. Again it was necessary to provide periodic samples that could be placed on life test by the Laboratories to ascertain that the manufacturing processes were under control. These samples, in all possible cases, were taken from product that would normally be rejected because of some minor defect, but which would not in any way detract from the validity of the life tests. The making of hard solder splices between nichrome resistance wire and gold-plated copper leads, and keeping ceramic parts from coming in contact with metal surfaces and thereby being contaminated because of the ceramic's abrasive characteristics, were two major problems on resistors. Fig. 7 indicates resistor yields.

Inductors

Inductors comprised 20 different designs, most of which were air core, but there were some for which it was necessary to cement permalloy dust cores into pockets of the methacrylate form, and thereafter using wire on a shuttle, wind by hand the turns required to produce an inductor. These varied from a very small inductor, smaller in diameter than a pencil, to a fairly large "figure eight" inductor with turns having a major diameter of about $1^{1}/_{4}$ inches. Each layer of a winding was inspected with a microscope to insure that the wire had not been twisted or kinked, or that the insulation was damaged or uneven. Some of the shuttles became fairly long so that they could hold the amount of wire required to make a continuous winding. The operator's handling of this shuttle, as she moved it down around the openings in the methacrylate part, or placed it on a bench to proceed with the interleaving tape, demanded considerable dexterity and concentration to ensure that the shuttle was not turned over, which in effect would put a twist in the wire. Although best known means were used to sort cores for their magnetic properties prior to the time a winding was made, the limits on the inductors themselves were so close that subsequently a large number of windings were lost. The best cores that could be selected, plus the best winding practice, could not produce 100% of the inductors within the required limits. Crazing of the insulation on the wire; cementing together of two methacrylate parts or of permalloy cores into pockets of methacrylate parts, and handling those inductors having long delicate leads, were the most troublesome items on this apparatus. Fig. 8 shows manufacturing yield for inductors.

Networks combined several codes of component apparatus, such as a mica and a paper capacitor, resistor, and an inductor. Six networks were used in each repeater unit consisting of two interstage networks, an input, an output, and two beta networks. They demanded a most delicate wiring job, in that stranded gold-plated copper wires had to be joined in a small pocket in methyl methacrylate, where the least heat can be applied; otherwise the methacrylate is affected. After soldering, a minimum amount of movement of the stranded wire was permitted, inasmuch as the soldered gold-plated copper wire becomes quite brittle.

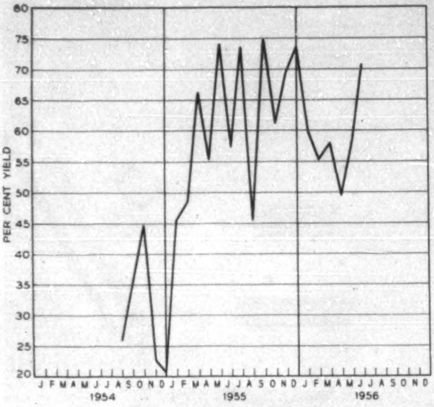

Fig. 5. Paper capacitor yield

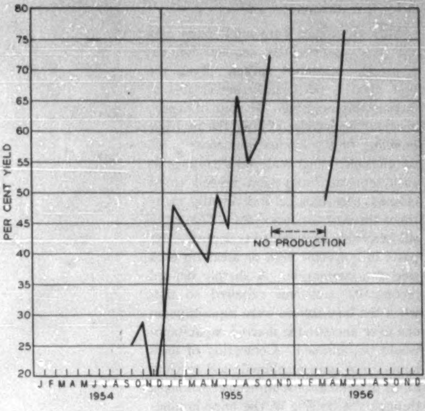

Fig. 6. Mica capacitor yield

REPEATER UNITS

Repeater units are wired assemblies consisting of 17 sections in which there are six networks, three electron tubes, one gas tube, one crystal, three high-voltage capacitors, one dessicator and two terminal sections. The successive build-up of these materials left little chance to make a repair because a splice in a lead was not permissible. It is during this assembly stage that a repeater receives its individual identity because of the frequency of the particular crystal assembled into the unit. A manufacturing yield of 100% was achieved in the assembly and wiring of repeater units.

It was necessary to calibrate the test equipment for this job very closely. Bell Telephone Laboratories and Western Electric worked at length to calibrate the testing details and the test sets for individual networks. Adjustments in components apparatus to bring the network to the fine tolerances required were accomplished by minute scraping of the silvered mica on a mica capacitor or removing turns from wire-wound inductors. The cementing of methacrylate parts, which was a troublesome item on mica capacitors and inductors, also had to be contended with on networks.

Packing and Shipping Co-ordination

Repeaters were packed in Western Electric specially designed 34-foot-long aluminum containers, weighing 1,000 pounds. Forty of these containers were made by an outside firm. Fig. 9 shows two containers tied down in a truck trailer. The repeaters were nested in a pocket of polyethylene bags containing shaped rubberized hair sections in order to cushion them during their subsequent handling and transportation. The instrumentation required with each case was tested, properly set, and inspected prior to its use on each outgoing case. The instruments were a shock recorder to register shocks in three planes, and a thermometer to register the minimum and maximum temperatures to which the repeater had been exposed. Arrangements were made with a commercial trucking company to provide three specially equipped truck trailers, which could be cooled by dry ice during hot weather and warmed by burning bottled gas during cold weather so as to control temperature within the 20 to 120 F called for in the repeater specification.

Appointment of a shipping co-ordinator supervisor added tremendously to the smooth functioning of services and provided the continuing vigilance required to protect repeaters and deliver them to the right place at the right time. His responsibility was to co-ordinate all the shipping information and arrangements from the time the item was ready for packing at the Hillside plant, through all trucking arrangements to the armoring factory, to the airport, to England, and to follow, with statistical data and reports, each enclosure up to the point at which it was possible to record the date on which the repeater was laid or stored in a depot.

Inspection Plan and Procedures

GENERAL

It is axiomatic that quality is not obtained by inspection but must be built into the product. However, the Inspection Organization does have the responsibility of certifying that the desired quality exists. Our evaluation indicated that the ordinary inspection screening would be inadequate to ensure the high degree of integrity demanded and that additional safeguards would have to be provided. These controls were achieved, in a practical way, by:

1. Selective placement, intensive training, and subsequent qualification testing of all personnel.
2. Inspection during manufacturing operations in addition to inspection of product after completion, and regulating inspection so that critical characteristics received repetitive examination during the process of manufacture and assembly.
3. A maintenance program for inspection and testing facilities which provided checks at considerably shorter intervals than is considered normal.
4. Inspection and operating records and reports that point out areas for corrective measures.
5. Records of quality accuracy for all inspection personnel as an aid in maintaining the high quality level.
6. Verification of all data covering process and final inspection as a certification of the accuracy of these data and certification that the apparatus satisfactorily meets all requirements.

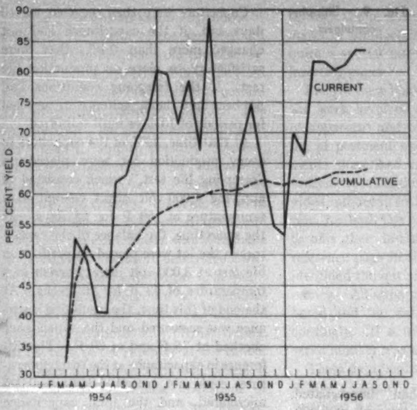

Fig. 7 (left). Resistor yield

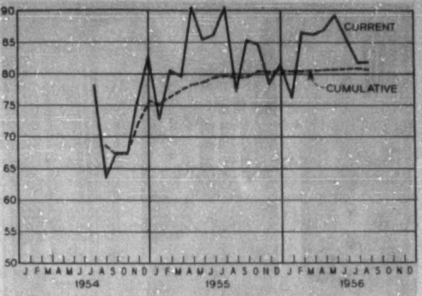

Fig. 8 (above). Inductor yield

Selection and Training of Inspection Personnel

The quality of a product naturally depends upon the skills, attitude, and integrity of the personnel making and inspecting it. It was realized that in order to develop the high degree of efficiency in the inspection organization necessary to ensure the integrity of the product, personnel of very high caliber would be required. The following qualifications were called for in these employees: 1. They would have to be experienced in similar or comparable work. 2. They would have to be precise, accurate and, above all, dependable. 3. In order to reduce the possibility of contamination and damage, they would have to be neat and careful. 4. They would require the ability to work in harmony with other employees, often as members of a team, in an environment where their work would be under constant scrutiny.

Most of the inspection employees selected to work at Hillside were transferred from the Kearny Plant and had an average Western Electric service of 12 years. They were hand-picked for the attributes outlined above, and the screening was performed by supervision through personal interviews supplemented by occupational tests given by the personnel department. These tests, which are in general use, are designed to evaluate background and physical characteristics, and they were given regardless of whether the employee had or had not previously taken them.

The following group of tests is an example of those given inspectors and testers of apparatus components:

1. Electrical: a-c—d-c theory and application.
2. Ortho-rater: Eye test for phoria, acuity, depth, and color.
3. Finger dexterity: Ability and ease of handling small parts.
4. Special: Legibility of handwriting, ability to transcribe data and to use algebraic formulas in data computations.

Inspection Plan

The general plan of visual and mechanical inspection consisted of:

1. Inspection of every operation performed, and in many cases partial operations, during the course of manufacture. This is of particular importance where the quality characteristics are hidden or inaccessible after completion of the operation.
2. Repeated inspection at subsequent points for omissions, damage, and contamination.
3. Rejection of product at any point where there was failure to obtain inspection or where the results of such inspection had not been recorded.

Most of the visual inspection was performed at the operators' positions to reduce to a minimum the amount of handling that could result in damage and contamination.

Visual inspection covered three general categories:

1. Inspection of work after some or all operations had been completed, such as the machining of parts.
2. Inspection at those points where successive operations would cover up the work already performed. An example of this is the hand winding of toroidal inductors where each layer of wire was examined under a microscope for such defects as twists, cracks, and crazes in enamel insulation, spacing and overlapping of turns, and contamination before the operator was allowed to proceed with another layer. While being inspected, the work remained in the holding fixture, which was hinged in such a manner as to permit inspection of both top and bottom of the coil. Inductors received an average of 13 and a maximum of 26 visual inspections during winding.
3. Continuous "over-the-shoulder" inspection, where strict adherence to a process was required or where it was impossible to determine, by subsequent inspection, whether or not specific operations had been performed. In these cases, the inspector checked the setup and facilities, observed to see that the manufacturing layouts were being followed, that the operations were being performed satisfactorily, and that specifications were being met.

Electrical Testing

The electrical testing, in itself, was not unusual for carrier apparatus, and it runs the gamut from d-c resistance through capacitance, inductance, and effective resistance, to transmission characteristics in the frequency band 20 to 174 kc. What was unusual were the extremely narrow limits imposed and the number and variety of tests involved as compared to those usually specified for commercial counterparts.

The following two examples will serve to illustrate the extreme measures taken to prove the integrity of the product:

The first example is one type of resistor wound with no. 46 mandrelated nichrome wire to a value of 100,000 ohms ±0.3%. This resistor received six checks for d-c resistance, five for instantaneous stability of resistance, and two for distributed capacitance, at various steps in the proc-

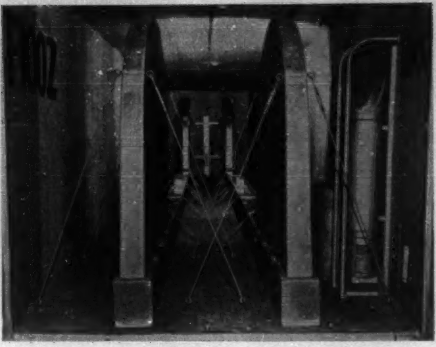

Fig. 9. Shipping containers

ess which included 6 days' temperature cycling for mechanical stabilization. This resistor was considered satisfactory, after final analysis of the test results, if: 1. the difference in any two of the six resistance readings did not exceed 0.25%, 2. the change in resistance during cycling was not greater than 0.02%, 3. the "instantaneous stability" (maximum change during 30 seconds) did not vary more than 0.01%. In addition, it was required that the distributed capacitance, minimum 7, maximum 10 micromicrofarads, should not differ from any other resistor by more than 2 micromicrofarads.

As the second example, for high-voltage paper capacitors, the 0.0004-inch-thick kraft paper, which constitutes the dielectric, was selected from the most promising mill lots which the manufacturers had to offer. This selection was based on the results obtained from tests that involve examination for porosity, conducting material, and conductivity of water extractions. These tests were followed by the winding and impregnation in Halowax of test capacitors. The test capacitors were then subjected to a direct voltage endurance test at 266 F for 24 hours.

Samples of prospective lots of paper, which have passed the foregoing test, were then used to wind another group of test capacitors that were subsequently impregnated with Aroclor and sealed; 1,500-volt direct current was then applied to the capacitors at 230 F for 500 hours. In case of failure, a second sampling was permitted.

After the foregoing tests had been passed, the supplier providing the particular mill lot was authorized to slit the paper. Upon receipt, six special capacitors were wound, using a group of six rolls of the paper being qualified. These capacitors were then impregnated, checked for dielectric strength at 3,000-volt direct current, and measured for capacitance and insulation resistance. The capacitors were then given an accelerated life test at 2,000-volt direct current, temperature 150 F, for 25 days. Each lot of six satisfactory test capacitors qualified six rolls of paper for use.

Product capacitors were then wound from approved paper, and the dry units checked for dielectric strength at 300-volt direct current. Capacitance was checked and units were then assembled into cans and ceramic covers soldered in place. Assemblies were pressurized with air, through a hole provided for the purpose, while the assembly was immersed in hot water to determine if leaks were present. Capacitors were then baked, vacuum dried, impregnated, pressurized with nitrogen, and sealed off. The completely sealed units were then placed in a vacuum chamber at a temperature of 150 F, 2-millimeter mercury, for 3 hours to check for oil leaks. Capacitance was rechecked and insulation resistance measured.

After 7 days, capacitors were unsealed to replenish the nitrogen that had been absorbed by the oil, resealed, and again vacuum leak tested. An X-ray examination was then made of each individual unit to verify internal mechanical conditions. Capacitors were then placed in a temperature chamber and given the following cyclic treatment:

$$\left.\begin{array}{l}\text{16 hours at 150 F}\\ \text{8 hours at 75 F}\\ \text{16 hours at 0 F}\\ \text{8 hours at 75 F}\end{array}\right\}\text{1 cycle}$$

At the end of 10 days, or 5 cycles, the insulation resistance and conductance were measured and a norm established for capacitance.

Capacitors were then recycled for 10 days and, if the capacitance had not changed more than 0.1%, they were satisfactory to place on production life test. If the foregoing conditions had not been met, the capacitors were recycled for periods of 10 days until stabilized.

At that time, 10% of the capacitors in every production lot were placed on "sampling life test," which consisted of applying 4,000-volt direct current in a temperature of 150 F for 25 days. At the same time, the balance of the capacitors in the lot were placed on production life test at 3,000-volt direct current in a temperature of 42 F for 26 weeks. At the end of this time, the insulation resistance was measured and the capacitance checked at 75 F and at 39 F. The difference in capacitance at the two temperatures could not exceed +0.001, −0.005 microfarad, and the total capacitance could not exceed maximum 0.3726, minimum 0.3674 microfarad. The capacitance from start to finish of the life test could not have changed more than ±0.1%.

If all of these requirements were satisfied, the particular lot of capacitors described was considered satisfactory for use in the product. The foregoing examples are typical of the procedures evolved for ensuring, to the greatest degree possible, the long, trouble-free life of all apparatus used in the repeater.

RADIOISOTOPE TEST

There were many new and involved tests developed and applied to the manufacture of repeaters. One of the unique tests is the use of a radioisotope for detecting leaks under hydraulic pressure.

The initial closure operations consisted of brazing into each end of the repeater housing a Kovar-to-glass seal. These seals are equipped with small-diameter nickel tubulations which were used to flush and pressurize the repeaters with nitrogen. After these operations had been performed, one of the tubulations was pinchwelded, overbrazed and coiled down into the seal cavity. The repeater was then placed in a pressure cylinder with the open tubulation extending through and sealed to the test cylinder. A mass spectrometer was then attached to the tubulation and the test cylinder pressurized with helium at 10,000 psi. At the conclusion of this test the repeater was removed from the test cylinder and, after breaking the desiccator diaphragm, the remaining open tubulation was pinchwelded and overbrazed. At this point, it became necessary to determine whether the final pinchweld and overbrazing would leak under pressure.

Since there was no longer any means of access to the inside of the repeater, all testing had to be done from the outside. This was accomplished by filling the glass seal with a solution of radioisotope cesium 134, which was retained by a fixture. The repeater was then placed in a test cylinder and hydraulic pressure applied, which was transmitted to the radioisotope in the fixture. After 60 hours under pressure, the repeater was removed from the cylinder and the seal drained and washed. An examination was then made with a Geiger counter to determine if any of the isotope had entered the final weld.

The washing procedure, after application of the isotope solution, involved some 60 operations with precise timing. In the case of the repeater at the rubber seal stage where both ends were tested, it was desirable that these operations be performed concurrently. This was accomplished by recording the entire process on magnetic tape which, when played back, furnished detailed instructions and exact timing.

Raw-Material Inspection

As might be expected, raw materials used in the project were very carefully examined and nothing left to chance. Every individual bar, rod, sheet, tube, bottle, or can of materials was given a serial number and a sample taken from each and similarly identified. Each sample was then given a complete chemical and physical analysis before each corresponding piece of material was certified and released for processing. In many cases, the cost of inspection far exceeded the cost of the material. However, the discrepancies revealed and the assurance provided more than justified the expense.

Detailed records of all raw-material inspection were compiled and furnished to the responsible raw-material engineer who examined them, critically, as an additional precaution before the material was released to the shop.

Inspection Records

To eliminate, as much as possible, the human element in providing assurance that all prescribed operations had been performed satisfactorily and inspected properly, and the results recorded, means were established to compile a complete history of the product concurrent with manufacture. This was accomplished through the provision of permanent data books of semilooseleaf design, which require a special machine for removing or inserting pages.

Each of these books covered a portion of the work involved in producing a piece of apparatus and contained a sequential list of pertinent operations and requirements prescribed in the manufacturing process specifications. Space was provided, adjacent to the recorded information, for both the operator and inspector to affix their initials and the data. A reference page in the front of each book identified the initials with the employees' names. All apparatus was serially numbered and the data were identified accordingly. If a unit was rejected, that serial number was not reused.

These data books, in addition to establishing a complete record of manufacture, provided a definite psychological advantage, in that people were naturally more attentive to their work when required to sign for responsibility.

Quality Accuracy

As pointed out previously, every precaution was exercised in selecting and training inspection personnel assigned to the project. However, it was realized at the outset that human beings are not infallible and that insurance, to the greatest degree possible, would have to be provided against the probability of errors in observation and judgment. Quality accuracy evaluation procedures were therefore established for determining the accuracy of each inspector's performance.

Quality accuracy checking was performed by a staff of five inspection representatives and involved an examination of the work performed by inspectors to determine how accurately it was inspected. Materials which the inspector accepted and those which had been rejected were both examined.

Verification and Summary of Data

As an added measure of assurance as to the integrity of the product, procedures were established for verifying and summarizing the inspection records for each serially numbered component, up to and including complete repeaters.

Verification involved a complete audit of the inspection records to provide assurance that all process operations were recorded as having been performed satisfactorily, that the prescribed inspections had been made, and the the recorded results indicated that the product met all of the specified requirements. This work was performed by a group of six inspection representatives who had had considerable experience in all phases of inspection and inspection records.

As the verification of a particular piece of apparatus proceeded, a verification report was prepared which, when completed, contained the most pertinent inspection data, such as:

1. Recorded measurements of electrical parameters.
2. Values calculated from measurements to determine conformance.
3. Confirmation that all process and inspection operations had been verified.
4. Identification (code numbers and serial or lot numbers) of materials and components entering into the product at each stage of manufacture.

The verification report usually listed the data for 20 serial numbers of a particular code of apparatus, along with the specified requirements. Included, also, was a cross reference to all the inspection data books involved so that the original data could be located easily. These verification reports were prepared for all apparatus up to and including the finally assembled and tested repeaters.

The following gives an indication of the number of items examined in the verification of one complete repeater:

Items verified in data books	17,593
Items verified on recorder charts	1,142
Calculations verified	1,580
Total	20,315
Number of entries on verification reports	4,070

Verification reports, in addition to presenting the pertinent recorded data, provided a "field" of 20 sets of measurements from which it was easily possible to spot a questionable variation. For example, it was the adopted practice on this project to examine critically any characteristic of a piece of apparatus, in a universe of 20, which varied considerably from the rest, despite the fact that it was still within limits.

While the number of cases turned up in the verification process which resulted in rejection of product are relatively few, it is believed that the added insurance provided, and the psychological value obtained, considerably outweighed the cost.

Power-Feed Equipment for the North Atlantic Link

G. W. MESZAROS H. H. SPENCER

Synopsis. Precise regulation of the direct current which provides power for the undersea repeaters in the new transatlantic telephone cable is necessary to maintain proper transmission levels and to assure maximum repeater tube life. The highest possible degree of protection is needed against excessive currents and voltages under a wide variety of possible fault conditions. Furthermore, to minimize the dielectric stresses, a double-ended series-aiding power feed must be used, and the balance of these applied voltages must be maintained despite substantial earth potentials. This paper describes the design features which were employed to attain these objectives simultaneously, while eliminating, for all practical purposes, any possibility of even a brief system outage because of power failure.

THE PRINCIPAL objectives in the power plant design for the transatlantic cable system were as follows:

1. To stress reliability in order to guarantee continuous d-c power to the electron tubes that form an integral part of the submerged repeaters. This is essential, not only to be able to maintain continuous service, but also to prevent cooling and contraction of the repeater components, especially the tubes.

2. To provide close d-c cable-current control to ensure constant cathode temperature and regulated plate and screen potentials for the repeater tubes. These operating conditions are essential to obtain both maximum life from these tubes and constant transmission level.

3. To control and limit the applied d-c cable potentials to minimize the dielectric stresses. The life of certain capacitors in the repeaters is critically dependent upon these stresses. Moreover, momentary high potentials increase the chances of corona formation and insulation breakdown.

4. To protect the cable repeaters from the excessive potentials or currents to which they might be subjected after an accidental open or short circuit in the cable.

5. To compensate for earth potentials up to 1,000 v (volts), of either polarity, which may develop between the grounds at Oban and Clarenville during the magnetic storms which accompany the appearance of sun spots and the aurora borealis.

6. To provide adequate alarms and automatic safety features to ensure safe current and voltage conditions for both the cable and the operating personnel.

Design Requirements

Reliable Cable Power

The first basic problem of design was to select a reliable source of d-c power for energizing the cable repeaters. Although a string of batteries, on continuous charge, is perhaps the most dependable source of direct current, such an arrangement is not attractive here. A complex set of high-potential switches would be required for removing sections of batteries for maintenance and replacement purposes. Protection of the repeater tubes from damage during a cable short circuit would be difficult. Facilities to accommodate changing earth potentials would be cumbersome. Furthermore, the problem of hazards to personnel would be serious.

The use of commercial a-c power with transformers and rectifiers to convert to high-potential direct current would expose the cable to power interruptions even with a stand-by diesel-driven alternator, because of the time required to start the engine. A diesel plant could be operated on a continuous basis, but this prime power source would also present a considerable failure hazard even with the best maintenance care. The 2-motor alternator set, used so successfully in the Bell System's type *L* carrier telephone system, was adopted as representing the most reliable continuous power source available. This set normally operates on commercial a-c power, but when this fails, the directly coupled battery-operated d-c motor quickly and automatically takes over the drive from the induction motor to prevent interruption of the alternator output. Here the storage battery is still the foundation for continuity, but at a more reasonable voltage.

As described later, the possibility of a system outage resulting from failure of this 2-motor alternator set has been essentially eliminated by using two of these sets, cross-connected to the rectifiers which supply power to the two cables, with a continuously operating spare for each set, automatically switched in upon failure of the regular set.

The regulating features of the rectifiers will be described in a later section. In the present discussion of reliability it is sufficient to note that series regulating tubes are used, which are capable of acting as high-speed switches, through which two rectifiers can be paralleled. Thus, either rectifier can accept instantaneously the entire load presented by the cable. In each regulator, the series tubes carrying the cable current are furnished in duplicate and connected in parallel to share the cable load, a single tube being capable of carrying the entire load. These current regulators are operated from separate a-c sources to protect against loss of cable power because of failure of one of the sources of a-c power.

Cable Potentials

To minimize the cable potentials, half of the d-c power is supplied at each end of each cable, the supplies being connected in series aiding. With this arrangement, as shown in Fig. 1, the d-c cable potential at one end of each cable is positive with respect to ground, while at the other end the potential is negative. This places the maximum potential and risk on the repeaters near the shore ends, which are more readily retrieved, while the repeaters in the middle of the cable, in deeper water, have potentials very near to ground. The power equipment would be simpler with a single-ended arrangement, but at the penalty of doubling the dielectric stresses in the entire system, which would be prohibitive. A balanced power feed could have been attained at the expense of power-separation filters in the middle of the cable, or a shunt impedance of appropriate size at the mid-point. The resulting complications, including difficulty in the location of a cable fault, could not be justified for the sake of simplification of power-plant design and operation.

The requirement that minimum cable potentials be maintained during and after severe earth potential disturbances necessitates variable output voltages from the supplies at both ends, and this introduces problems in continuous voltage balance and regulation stability. The design features which yield the required performance are described in a later section.

D-C Cable-Current Regulation

The salient requirements in performance of the constant current regulator are listed as follows:

1. The regulator must have extremely fast response to hold the cable current within a few milliamperes of its nominal value should a short circuit develop in

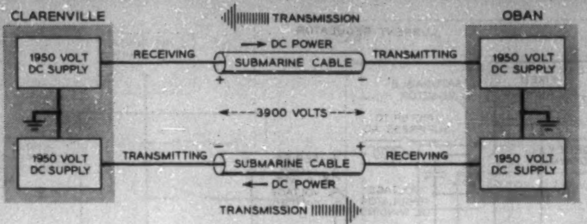

Fig. 1. Cable voltage supply

the cable. Thus, damage to the heaters of the repeater tubes, as well as excessive induced transient voltages in the repeater transformers, are avoided. The probability of a short circuit is greater near the shore ends where the water is shallow and sea traffic is a factor. The regulator must be capable of absorbing the reduction in power to the cable, while maintaining current control under normal conditions. This sudden exchange in power from cable to regulator may be as much as 2,000 v at 0.25 amp (ampere).

2. The cable current should be maintained constant within 0.2% (per cent) of its nominal value for normal variations in a-c supply, gradual earth-potential changes, and ambient-temperature changes. This degree of regulation allows an adequate safety factor in maintaining a constant transmission level.[1]

3. The regulators, with the power-separation filters and the rectifier filters, must limit the power-supply noise at the cable terminals to a peak-to-peak value less than 0.02% of the d-c supply potential.

4. The cable current must be adjustable over a range of 225 to 245 ma (milliamperes) to compensate for repeater-tube aging.[2]

5. The regulators must operate in parallel in such a way as to ensure continuity of power should one fail or be removed from service for maintenance. This of course implies that regulators can be switched in and out of service without causing surges in the cable current or voltage.

6. The series-aiding arrangement, with rectifiers at each end of the same cable, must be stable.

7. The regulators should be capable of being serviced at low potentials when in the test position to protect maintenance personnel.

8. The current regulator should be of the fail-safe type so that impairment of any of the regulator components will not permit excessive rise in cable current. In the event of component trouble, an aural or visual alarm should occur.

It was decided that a high-speed electronic constant-current regulator backed up by a slower speed servo system, as shown in Fig. 2 and discussed in detail later, would best meet these requirements. In this way, fast response with high gain is combined with wide regulating range, yet the efficiency is high and the load-handling capacities of the various components are held to a minimum. With regard to simpler alternatives, the electromechanical-type current regulator which uses relays and a motor-driven rheostat is too slow to protect the repeater tubes from a cable short circuit and its accuracy is insufficient to meet the regulation requirements. The all-magnetic type of regulator is possibly most dependable, but it does not readily provide either the speed of response or the wide regulating range needed.

General Description

Prime and Stand-by Power Source

Commercial service is considered the normal prime source of power for the cable, although at the Clarenville terminal commercial power was not available at the time of installation. Anticipating this condition, a reserve plant consisting of three 60-kw diesel alternators was installed and the distribution circuits were arranged, as shown in Fig. 3, to provide partial or total use of the commercial service. Initially, all cable power was supplied by diesel operation, alternating the prime movers on a weekly basis. These sets are paralleled manually, when they are interchanged, to prevent an interruption in the 60-cycle sypply. It may be noted that engine no. 1 is arranged as an automatic stand-by whether prime power is provided by diesels or by commercial service.

The switching and distribution arrangements are designed to be essentially failure-proof. At Clarenville, for example, two a-c distribution cabinets, each capable of being fed from two sources, were provided in separate locations. The normal source through engine no. 1 control bay can be readily by-passed directly to the manual diesels should engine no. 1 control bay be disabled. Furthermore, allocation of charging rectifiers, control circuits, a-c motors for continuity sets, etc., has been made in such a manner that loss of one cabinet alone will have minimum effect on the cable power supplies or office loads. At Oban, where 50-cycle commercial service is normally used, special distribution arrangements have been provided to give maximum power-supply reliability, with three manually operated 50-cycle 90-kw diesel-alternator sets arranged for stand-by service. The diesels, at this terminal, are larger to care for greater local power loads.

Continuous A-C Power From 2-Motor Alternators

At both cable terminals, two reliable a-c busses supply power to the d-c cable regulating bays. Each of these busses is fed from a continuously operated, self-excited, single-phase 230-v alternator, normally driven by a 3-phase induction motor on the same shaft with a 130-v d-c motor. Each regular alternator is backed up by a similar emergency alternator running at no load. A fifth motor alternator is provided, which can be used whenever any other set is out of service for routine maintenance or repair.

As alternator loads are essentially constant and since induction motor speeds are fairly insensitive to power-supply voltage variations, alternator outputs are set by fixed adjustments of their field rheostats. Supply voltages are monitored to control automatic transfer to d-c motor drive whenever the supply voltage drops below 80% of the normal value. Fig. 4 shows the normal running circuit for an alternator set, with the d-c motor connected to the battery through a resistance of 75 ohms inserted in the armature circuit. The field resistance *FR* is preset so that, when the battery is driving the set, the speed matches that of the a-c drive when the battery voltage is at the mean discharge value. During a-c drive, the emf (electromotive force) generated in the d-c motor armature is a few volts below that of the battery. Accordingly, when the fast-acting contactor *AR* shorts the 75-ohm resistance in the armature circuit, the motor finds itself essentially at the desired operating flux condition, and a smooth pickup of drive occurs. Oscillograms indicate that the interval between failure of a-c power and operation of contactor *AR* is less than 0.1 second. During the transfer from a-c to d-c drive, the change in the nominally 230-v output is less than 5 v.

Return to a-c drive is delayed approximately 20 seconds after the a-c supply voltage has returned to normal to allow time for the alternating current to stabilize. Fixed field settings for both d-c

motor and alternator fields provide simple control arrangements without the overspeed or overvoltage hazards which automatic regulators might add. Alternator output is monitored, however, to give alarms for voltage changes exceeding ±5% and to control transfer to d-c drive if the output should drop more than 10% for any reason. When the latter occurs, the machine locks on d-c drive. This feature guards against a-c motor failure or low a-c drive speed because of low supply frequency without low supply voltage.

Failure of the alternator output after transfer to d-c drive causes the set to stop and automatically transfer the load to its emergency alternator. This transfer causes a break in the alternator supply to its bus, but cable power is maintained constant by the parallel d-c regulating bay fed from the other alternator bus.

Battery Plants and Distribution

Battery power for d-c motor drive is supplied from a 66-cell 1,680-amp-hr (ampere-hour) battery at Clarenville, and from two 68-cell 1,680-amp-hr batteries at Oban. The latter station has double capacity to provide stand-by power for the a-c supplies to the inland transmission equipment.

At both cable terminals, control battery for the small alternator plants and the cable d-c regulating equipment provides 24 v and is split so that a fuse or a battery failure on either supply will not interrupt cable power. To guard against so remote a hazard as loss of a common battery for this vital control, two separate 24-v power plants have been provided with one half of the critical control circuits furnished from each plant.

In addition to supply d-c motor power, the 130-v battery at Clarenville supplies current to the carrier terminal and test equipment through voltage-dropping resistors which are normally in the circuit to hold the load voltages below a maximum of 135 v. These resistors are automatically short-circuited to maintain a minimum load voltage of 125 v when the battery voltage drops. A voltage-detecting relay also steps the fixed field adjustment of each d-c motor when the battery nears its final discharge voltage so that d-c motor speed is kept within about ±3% of normal a-c drive speed during battery operation. The 66-cell battery is floated at 143 v by means of voltage-regulated rectifiers and, after a discharge, is recharged by automatic operation of a regulated 100-amp motor generator set. As indicated in Fig. 3, the rectifiers for this plant are connected so that loss of one service cabinet will still leave sufficient charging capacity to float the load from the other cabinet.

Rectifiers and Associated Controls

As mentioned previously, each cable is supplied at all times by two regulating bays in parallel, each operating from a separate a-c source and each capable of taking over the cable load should the other fail. Thus, failure of an alternator supply or of a regulating bay itself will not interrupt the cable power. A spare regulating bay for each cable is arranged to replace either of the two regular bays and may be connected in parallel with the other two without overloading the associated 2.5-kva alternator.

As shown schematically in Fig. 2, the a-c supply to the rectifiers is controlled by a continuously tapped variable autotransformer, operated normally by a 2-phase low-inertia reversible motor, with provision for manual adjustments also. The autotransformer output is stepped up and rectified by a series arrangement of rectifiers, each to give a maximum of 550 v each, for a total of 2,750 v when the autotransformer is at the upper limit. The high-voltage rectifier output is filtered and supplied to the cable through the current regulating unit, cable connecting switch, and common cable control circuit. The cable current is regulated by controlling the plate to cathode drop across the electron tubes through which this current flows. A d-c amplifier, which derives its signal from a resistance in series with the

total cable current, varies the grid bias of the series regulating tubes. The series tubes have a control-drop range from about 150 v to the full supply voltage, the d-c amplifier being capable of driving the regulating tubes of cutoff. However, to protect the series tubes and to keep them operating at practically a constant plate voltage of 300 v, a servo system automatically raises and lowers the output from the autotransformer by means of the motor-driven a-c control unit, whenever the series-tube plate voltage varies more than 25 v from the normal value. For example, a 2% change in input alternating current would change the rectifier output of 2,300 v, which corresponds to a cable supply voltage of 2,000 v, by 46 v, which would increase the series-tube drop to 346 v. This increase in voltage would raise the signal current through the control winding of a saturable reactor which forms one leg of a balanced bridge in the a-c motor control circuit, and thus cause the autotransformer to be driven down, lowering the rectifier output until the series-tube drop is restored again to approximately 300 v.

OVERVOLTAGE AND OVERCURRENT PROTECTION AND ALARMS

While the power for the cable is electronically regulated, protective features are provided to guard against abnormal cable current or voltage. The first order of protection is a ±2% cable-current alarm, given by a voltage relay, which operates from the drop across a resistor in the ground-return circuit to the d-c bays. A second voltage relay, set for 5% high cable current, also monitors the current in the ground-return side, and with the current monitors in the high-voltage side it limits the cable current by operating the motor-driven autotransformers until the current is within 5% of normal. The voltage of the ungrounded side, however, is much too high for directly connected voltage or current relays. Therefore, magnetic amplifiers have been used to obtain isolated metering of the cable current. Two of these devices measure the current in the ungrounded side of the common power-supply lead to the cables. Of the three current monitors available, two must operate before turndown functions to prevent false turndown because of faulty metering.

Voltage protection is provided by means of magnetic amplifiers in shunt across the common power supply to the cable. Here, three monitors are arranged so that any two can reduce power, by means of the turndown control, if the voltage rises to the maximum allowable value for which the voltage relays are adjusted. These monitors draw about

1.5 ma each, but are connected on the supply side of the cable-regulating resistance so as not to affect cable regulation. They guard against excessive voltage resulting from an open circuit where voltages approximately 4,000 v could otherwise occur. They also guard against high voltage caused by earth potentials or unbalance between voltages at opposite ends of the cable. When set for a ceiling voltage of 2,600 v, a maximum of 3,000 v occurs on open circuit on the first rise, after which the voltage holds within 2,600 ±200 v as the turndown relays operate and release to maintain the ceiling voltage. A fourth magnetic-amplifier voltage-detecting relay provides an alarm for ±5% excursions in cable voltage from the normal value. Other alarms are provided to indicate low output in either of the two parallel regulating bays, relay troubles, loss of magnetic-amplifier a-c control voltage, and fuse failures.

To limit the rate of change in the cable current under short-circuit conditions and to reduce the rise in voltage at the repeaters on open-circuit failure, an inductance of about 36 henrys is connected in series with the cable circuit, and physically close to the cable termination, so that any failure in the power supply would have the advantage of this surge-limiting element.

METERING

Metering of the cable current is a very important part of the power-plant design. Not only are the cable-current ammeters needed to set the value of current desired, but also their ability to indicate absolute current values assists in obtaining stable regulation between the two ends of the cable. The meters provided for this purpose are suppressed-zero, magnetically and statically shielded, 150- to 300-ma large-scale ammeters, with 0.5% accuracy. One of these meters is connected in the ungrounded side and another in the grounded side of the cable supply circuit to provide an accuracy check and to indicate any ground-leakage current in the supply circuit. They are connected to highly accurate, 1.0-ohm 4-terminal shielded resistors, acting as shunts in the cable-current circuits, with their shunt leads arranged for switching to a calibration box for checking accuracy and adjustment. This box uses a Weston laboratory standard cell, which is essentially a single-point potentiometer with the usual galvanometer, acting as a calibration standard at the 225-ma point. Meters calibrated at Oban for 225 ma were expected to be within 0.2% or 0.5 ma of those similarly calibrated at Clarenville, and, at present, are within about 0.2 ma.

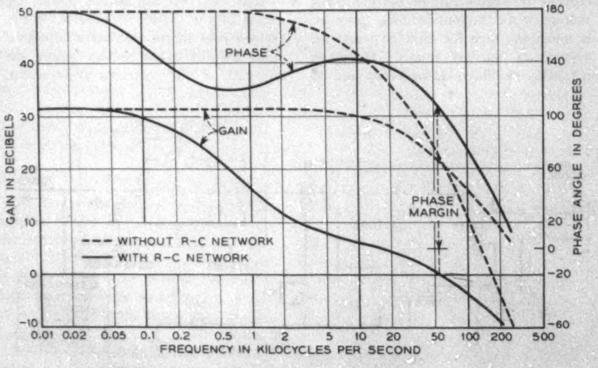

Fig. 6. D-c amplifier gain and phase, experimental model

The cable current is also indicated by a recording ammeter. Meters in each regulating bay indicate the division of current between paralleled regulators. These meters have only 1.0 % accuracy but are satisfactory for adjusting load balance between parallel bays and also are used in the turn up of power on a particular bay.

Cable voltage is read on a large-scale voltmeter reading 0 to 3,000 v and having ±0.25% accuracy. Since the accuracy is not critical, this meter is not arranged for calibration. However, the series resistors incorporate 6,000-v components for an extra degree of reliability. The voltmeter, with its series resistance, is normally connected across the common cable power supply, ahead of the cable

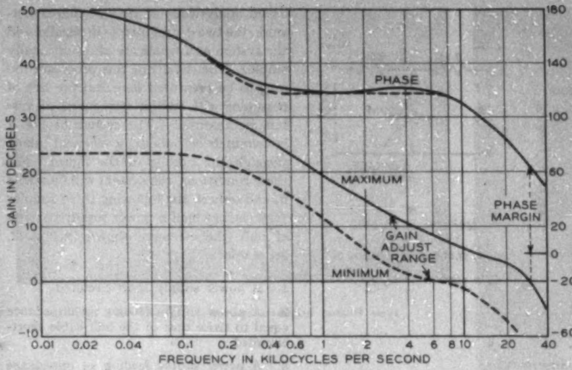

Fig. 7. D-c amplifier gain and phase, production model

current regulating point. It can, however be switched to read the cable voltage nearer the cable termination. In the latter position, it reduces the cable current by about 1.0 ma, causing an unbalance in cable regulation, and therefore is not normally left in this position. The cable supply voltage is also indicated by a recording voltmeter.

Other meters are provided to indicate series-tube plate voltages, d-c rectifier voltages, a-c input voltages, series-tube currents, test currents for adjusting magnetic-amplifier operating limits, and the difference in current between the positive and negative power supplies to ground. Since many of these instruments operate at high potential a special design was used, with the operating mechanism and scale depressed in the instrument case approximately 1.0 inch. This eliminated possible electrostatic effects on the instrument pointers, and served as a safety measure.

D-C Regulation

D-C Amplifier

The direct-coupled 2-stage amplifier, shown in Fig. 5, is characterized by potentiometer coupling and cold-cathode gas-tube voltage stabilizers. The biases are selected high enough so that linear operation is assured even for a short circuit at the cable terminal. As is apt to be the case in a direct-coupled amplifier, cathode temperature in the low-level stage is critical. In this amplifier, a 5% change in heater voltage results in a 0.5-ma change in the cable current.

The required precision of current regulation in these power supplies can be expressed as representing a source impedance of not less than 100,000 ohms. To meet this requirement, the gain of the d-c amplifier was made as large as practicable with the plate and screen potentials available from gas-tube regulators. Interstage network impedances are high to reduce the shunt losses, and are proportioned to provide the large biases mentioned previously. Gain adjustment is provided by a variable resistance in series with the cathode of the first stage.

Shaping of the loop gain and phase characteristics to obtain margins for stable operation is accomplished by means of the *RC* shunt, (R_9C_1), across the plate resistor for the first stage. The amplifier gain and phase characteristics without this compensation are shown in Fig. 6. These data were obtained by opening the feedback loop at the control grid of the first stage, applying normal d-c bias and a variable frequency a-c signal to the grid of the tube, and measuring the magnitude and relative phase of the return signal.

The corresponding characteristics with the compensating network in place are also shown in Fig. 6. The compensating network effectively puts a relatively low-impedance shunt across the interstage network at the higher frequencies, resulting in a "step" in the gain characteristic. A secondary effect is the phase shift in the transition region. The calculated "corner frequencies" are 2,800 and 195 cps (cycles per second), respectively, chosen on the basis of the criteria: 1. little effect on regulator gain at 100 or 120 cps, the most prominent rectifier ripple frequency, and 2. a gain step of something about 20 db (decibels) with no appreciable contribution to the phase shift at frequencies above 30 kc. The calculated loss at 120 cps is 1.2 db, with a maximum phase shift of about 60 degrees at the median frequency. These results agree quite well with the measured data plotted in Fig. 6.

As indicated in Fig. 6, the phase margin at the gain crossover frequency of 55 kc was somewhat over 100 degrees for the experimental model on which these measurements were made. The gain margin could not be measured readily, but is

clearly substantial. On production units, larger wire sizes and longer lead lengths resulted in lesser, but still satisfactory stability margins, as shown in Fig. 7, where the phase margin is somewhat over 60 degrees. Fig. 7 also shows the characteristics at the extremes of gain control, where the range of control is about 8 db.

Fig. 8 shows the measured performance of the d-c regulators, the servo system being disabled to obtain a plot of the performance of the d-c amplifier and associated circuits. Twenty-two regulator units were manufactured and measured, and the curves of Fig. 8 show the extreme limits observed, with the differences between individual regulators caused primarily by differences between electron tubes. The measured range of source impedance, 130,000 to 170,000 ohms, allows margin for regulator-tube aging above the 100,000-ohm objective.

A-C SERVOMECHANISM

As noted previously, the servo system shown in Fig. 2 is part of the current-regulating scheme and holds the series-tube plate potential within reasonable limits by adjusting the rectifier input voltage. In an emergency, a turndown feature, operated either manually or automatically from several remote points will reduce the autotransformer output to zero in less than 2 seconds. For simplicity, only the manual turndown feature is shown in Fig. 2. It operates simply by switching one end of the motor control winding from one corner of the bridge to the other, thus applying half of the input voltage to the control winding.

Manual operation of the autotransformer tap is provided to raise the cable current slowly, either initially or after a turndown. In manual operation, a dynamic brake which consists of a short circuit on the motor control winding prevents the motor from creeping or coasting when the operator releases the handwheel, as it otherwise would since the fixed phase of the 2-phase motor is always energized. The turndown feature takes precedence over the short circuit of the motor control winding, automatically, to energize the motor should the operator inadvertently cause abnormally high cable voltage or current.

One essential feature of the servo design is the dead band of the series-tube plate voltage in which the servo remains stationary, even though there are small changes in the incoming signal. This band can be varied from 10 to 100 v under control of a gain-adjust potentiometer across the control winding of the 2-phase motor. Without this dead band, the servo would be constantly in operation correcting for small random variations in line voltage or earth potentials. Furthermore, since it is extremely difficult to set the current regulators at the two ends of a cable to exactly the same current, the servo dead band permits some margin of error. Otherwise, the servo associated with the current regulator, which is trying to regulate for a slightly higher cable current, would drive its rectifier voltage to its stop or maximum output, unbalancing the cable voltages.

SYSTEM STABILITY*

A complete analysis of system stability represents an exceedingly formidable, if not impossible, task. It has been established analytically that, for a linear network, the two d-c regulators in parallel and the system as a whole are unconditionally stable. The details of this proof are too long to be presented here, but the line of reasoning with respect to the over-all system is presented. The system of Fig. 1 is symmetrical about a vertical plane through the middle of the figure. For these conditions, the system will be stable if, and only if, the following three simpler systems, in which a power supply consists of only the elements shown in Fig. 2, are stable:

1. A power supply short-circuited.
2. A power supply feeding an impedance equal to twice that of the half cable short-circuited.
3. A power supply feeding an impedance equal to twice that of the half cable open-circuited.

The transfer function of the servomechanism was measured over the frequency range of principal interest, zero to one cps. The behavior near zero frequency was determined from the asymptotic slope of the unit step response. During time-domain measurements, it was quite apparent that the a-c control loop could be considered as a linear network only in an approximate sense, and thus that the analytical results were primarily useful in interpretation of observed behavior of the system. In this frequency range the d-c amplifier gain is a real constant, flat gain, and negligible delay as previously shown. Therefore, only the a-c servo-feedback loop characteristic has to be known to predict the stability of condition 1. The Nyquist loop for this transfer function shows that condition 1 is satisfied. A similar examination of the Nyquist plot, including the readily computed cable impedance shows that conditions 2 and 3 are satisfied. Thus the linear analysis indicates stable operation for the system of Fig. 1. This result was confirmed by tests of conditions 1, 2, and 3, individually and by the behavior of the system as a whole, both in the laboratory with a simulated power network for the cable, and in the final installation.

One of the most obscure aspects of the power-system behavior is that of equilibrium conditions after one or a series of large earth-potential disturbances. While the system is stable, in the sense that the transient due to a perturbation will disappear in a finite time once the disturbance has been withdrawn, the range of possible equilibrium positions (disregarding the overvoltage protective feature) is extremely wide, from perhaps 1,300 to 2,500 v at the cable terminals. The upper

---

* The analysis, briefly summarized, was made by C. A. Desoer.

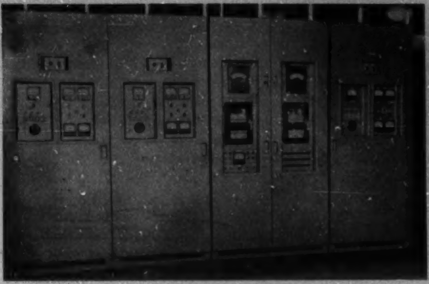

Fig. 10. D-c regulator and common control bays

limit of 2,500 v is set by the maximum output available from one power plant. This also sets the lower limit of the associate power plant at the far end of the cable. This situation is illustrated diagrammatically in Fig. 9.

The behaviors of the servomechanisms at the two ends of a given cable are nearly enough alike that the repeated introduction of simulated earth potential in the laboratory was found not to disturb substantially the equilibrium point. This was true for earth potentials of either polarity up to 1,000 v and with these potentials introduced at any point along the artificial cable. A rate of change of earth potential of 20 v per second was adopted in these tests, with the thought that such values would be realistic.

With regard to the long-term stability of the equilibrium condition as described, it is, of course, important that the controls which establish the cable current at the two ends of the same cable be adjusted for very nearly the same value. Unless this is done, the cable voltage at one end will gradually increase or decrease, and the voltage at the other end will move equally in the opposite direction. This would eventually bring in alarms and necessitate manual readjustment. In this connection, the voltmeters which indicate the drop through the series regulating tubes provide a very convenient magnification of any drift in cable current. The multiplying factor is the effective d-c impedance of the regulated system, i.e., more than 100,000 ohms. Thus 25 v, which is an appreciable fraction of the nominal 300 v across the series regulating tubes, is equivalent to less than 0.25 ma which is of the order of 0.1% of normal cable current. As a matter of fact, the behavior of this voltage provides the final criterion for precise adjustment of cable current to assure long-term stability.

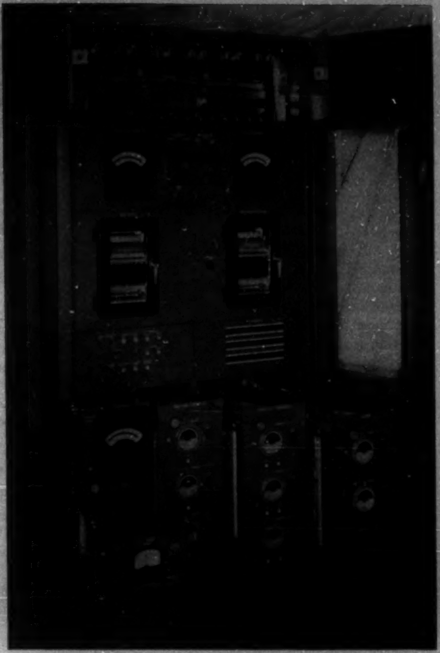

Fig. 11. Common control bay

Equipment Design

DESCRIPTION

Fig. 10 shows the complete d-c equipment for supplying one polarity of power to one cable. Similar equipment provides the opposite polarity to the other cable. The two equipments are located facing each other across a common aisle, with their common control bays directly opposite. Regulator 1, on the right, is normally operated in parallel with regulator 2. Regulator 3, on the left, is the spare regulator, and is normally off. The common bay, between regulators 1 and 2, includes the cable termination and power-separation filter. This equipment and all live parts of the circuit, back to the common point to which the switches in the individual regulator bays are connected, is enclosed in a high-voltage compartment.

The paralleling control switches are mounted in high-voltage compartments in their respective regulating bays and must remain completely enclosed, as their common cable connections are alive during cable operation. These switches have an interrupting capacity of 1.0 amp at 3,000 v, thus providing a large safety factor over the 0.245-amp maximum load current.

Fig. 11 illustrates some of the special design features built into the equipment to facilitate maintenance. The high-voltage compartment, shown open at the top, is locked whenever the cable is in operation, and this protection feature will be described. Pull-out drawers at the bottom contain metering shunts, a test unit for adjusting voltage and current-protection limits, a voltage-protection unit, a current-protection unit, and an alarm unit. While only one of these compartments is to be pulled out at a time, they are arranged so as not to endanger personnel or to affect service during adjustment when they are open. Doors are provided on all bays to prevent accidental disturbance of adjustments and to protect against damage to controls.

CORONA

The high-voltage a-c elements of the complete regulator bays were tested for corona with 4,000 v of alternating current applied. Furthermore, if corona was observed upon increasing the applied rms voltage to 5,000 v, it was required to extinguish when the voltage was reduced to 3,500 v. The maximum acceptable leakage was 20 μa (microamperes) at 4,000 v across the circuit (200 megohms). A d-c corona requirement of 4,000 v was applied to the d-c elements of the regulator bays and 5,000 v for the common bay, with a maximum permissible leakage of 5 μa. The higher corona requirements on the common bay were intended to eliminate the necessity for turning down the entire system for repair. A high standard of workmanship is required to provide such performance. There can be no sharp projections and no loose strands of wire. Solder must be applied in such a way as to obtain a rounded smooth joint, and high-voltage wiring must be dressed away from exposed grounded metal, bus bars, etc., so that the outer braid, other than polyethylene, does not come in contact with metal.

CROSSTALK AND OUTSIDE INTERFERENCE

To meet the severe crosstalk requirements between receiving and transmitting circuits and to guard against feeding office-noise potentials into the carrier transmission system, arrangements were made so that office grounds are carefully separated from the outer conductor of the cable and from all circuit elements within the power-separation filter. Pickup of external radio-frequency fields by the power-separation filters was greatly reduced by completely enclosing the cable terminal and the power-separation filter elements nearest to the terminal in a copper shield. The shielding itself and the cans of power-separation filter capacitors and oil-filled coils are connected to the return tape of the cable which is insulated from office ground until it reaches sea water, thus reducing the coupling to the other cable, as compared with tying both tapes together at the office or bay frame ground.

PROTECTION OF PERSONNEL

A key-locking system is provided to safeguard against any hazard to personnel from high voltages. In the common bay, the high-voltage compartment can be entered only by operating a switch which short-circuits the cable to ground and releases a key for the compartment doors. In each regulating bay, the key system assures that the bay is disconnected from the cable and hence from the paralleling power supplies. Where access is required to the interior of any compartment, the key system insures that the a-c power to the bay also is switched off.

The test compartment contains pin jacks, provided for maintenance operations, which are always performed with the regulator bay connected to a low-resistance load. Access to this compartment can be obtained with a-c power connected to the bay. However, for such access, the key system enforces the operation of the output disconnect switch, which also transfers the bay to a low-resistance load. Moreover, a mechanical interlock with the autotransformer assures that the test voltages are reduced to safe values.

Besides its function in protecting personnel, the key system also insures that no more than one regulating bay is disconnected at one time so that continuity of service is protected at all times by two parallel regulators.

Factory and Ship Cable Power

Besides the cable power supplies at the ocean terminals, similar d-c cable current-regulating equipment was designed for use at the cable factory and abroad the cable ship *Monarch*. Well-protected and closely regulated reliable power was considered essential during the cable loading and laying operations. It was necessary to have power on the cable continuously, except when splices were made, in order to detect a fault immediately, to measure transmission characteristics for equalization purposes, and finally to alleviate the strain on the glassware and tungsten filaments of the repeater tubes during the difficult laying period.[3]

Electron Tubes for the Transatlantic Cable System

J. O. McNALLY G. H. METSON E. A. VEAZIE M. F. HOLMES

Synopsis: Electron tubes for use in repeatered underwater telephone cable systems must be capable of operating for many years with a reasonable probability of proper functioning. In the new transatlantic telephone cable system the section of the cable between Nova Scotia and Newfoundland contains repeaters developed by the British Post Office Research Station at Dollis Hill. These repeaters are built around the type-*6P12* tube developed at that research station. The repeaters contained in the section of the cable system between Newfoundland and Scotland are of Bell System design and depend on the *175HQ* tube developed at Bell Telephone Laboratories. In this paper the philosophy of repeater and tube design is discussed, and the fundamental reasons for arriving at quite different tube designs are pointed out. Some of the tube development problems and the features introduced to eliminate potential difficulties are described. Electrical characteristics for the two types and life test data are presented. Fabrication and selection problems are outlined and reliability prospects are discussed.

ELECTRON TUBES suitable for use in long submarine telephone cables must meet performance requirements that are quite different from those imposed by other communication systems. In the home entertainment field, for example, an average tube life of a few thousand hours is generally satisfactory. In the field of conventional land-based telephone equipment, where the replacement of a tube may require that a maintenance man travel several miles, an average life of a few years is considered reasonable. In deep-water telephone cables, such as the new transatlantic system, the lifting of a cable to replace a defective repeater may cost several hundred thousand dollars and disrupt service for an extended period of time. These factors suggest as an objective for submerged repeaters that the tubes should not be responsible for a system failure for many years, possibly 20, after the laying of the cable. Such

very long life requirements make necessary special design features, care in the selection and processing of materials that are used in the tubes, unusual procedures in fabrication, detailed testing and long aging of the tubes, and the application of unique methods in the final selection of individual tubes for use in the submerged repeaters.

As indicated in the foreword and discussed at length in companion papers, the British Post Office developed the section of the cable system between Clarenville, Newfoundland, and Sidney Mines, Nova Scotia. This part of the transatlantic system used the *6P12* tube which was developed at the General Post Office Dollis Hill Research Station. The submerged portion of this system contains 84 tubes in 14 repeaters. Bell Telephone Laboratories developed the part of the system between Clarenville, Newfoundland, and Oban, Scotland. This section requires 102 repeaters, including 306 tubes, of a type known as the *175HQ*. Although a common objective in the development of the two sections has been to obtain very long life, the tube designs are quite different.

The Bell System decided on the use of a repeater housing that could be treated as an integral part of the cable, to facilitate laying in deep water. The housing is little larger than the cable and is sufficiently flexible to be passed over and around the necessary sheaves and drums. In such a housing the space for repeater components is necessarily restricted. This space restriction, combined with the general philosophy that the number of components should be held to an absolute minimum and that each component should be designed to have the simplest possible structural features, has resulted in the choice of a 3-stage 3-tube repeater. In this design, each tube carries the entire responsibility for the continuity of the service.

The Post Office Research Laboratories, prior to the development of the transatlantic cable system, had concentrated their efforts on shorter systems for shallow water. The placing of the repeaters on the bottom did not present the serious problems of deep-sea laying, so more liberal dimensions could be allowed for the repeater circuit. A 3-stage amplifier was developed which consisted of two strings of three tubes each, parallel-connected, with common feedback. The circuit was so designed that almost any kind of tube failure in one side of the amplifier caused very little degradation of circuit performance. This philosophy of having the continuity of service depend on two, essentially independent, strings of tubes has been carried over to the repeater design for the Clarenville–Sidney Mines section of the transatlantic cable.

In the Post Office system containing 84 tubes in the submerged repeaters, five tube failures randomly occurring in the system will result in slightly over 50% (per cent) probability of a system failure; one tube failure in the 306 tubes in the Newfoundland-Scotland section of the system will result in certain system failure. It is not surprising therefore to find the tube designed for the Newfoundland-Scotland section of the cable to have extremely liberal spacing between tube elements, to minimize the hazards of electrical short circuits. This results in a lower transconductance than is found in the tubes designed for the Nova Scotia–Newfoundland link. Other factors in the design will be recognized as reflecting the different operating hazards involved.

Early models of the British Post Office and Bell Laboratories tubes, together with the final tubes used in the cable system, are shown in Fig. 1.

Tubes for the Newfoundland–Scotland Cable

EARLY DEVELOPMENT CONSIDERATIONS

In Bell Telephone Laboratories, work on tubes for use in a proposed transatlantic cable was started in 1933. This was preceded by a study of what type of tube would best fit the needs of the various proposed amplifier systems, and by consideration of what might be expected to give the best life performance.

At the time this project was started, reasonably good tube life had been established for the filamentary types used in Bell System repeaters. Some groups of tubes had average lives of 50,000 or 60,000 hours (6 or 7 years). Equipotential cathode tubes were not then used extensively in the telephone plant, and there was no long-life experience with them. However, there appeared no basic reason why inherently shorter thermionic life should be expected, using the equipotential cathode, and there were several advantages in its use. One was the greater freedom in circuit design afforded by the separation of the cathode from the heater. Also there was the possibility of operating the heaters in series and using the voltage drop across the heaters for the other circuit voltages. It was felt, in addition, that the over-all mechanical reliability would be greater if the cathode were stiff and rigidly supported.

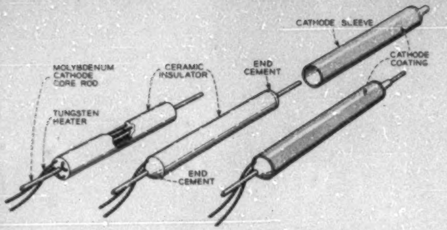

Fig. 3. Heater, heater insulator, and cathode assembly of 175HQ tube

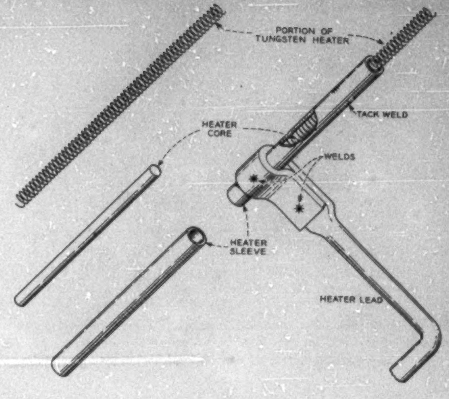

Fig. 4. Heater tabbing arrangement of 175HQ tube

The first equipotential tubes made were triodes. They were designed for use in push-pull amplifiers wherein continuity of service might be retained in case of a tube failure. This circuit was abandoned in favor of a 3-tube feedback amplifier that was the forerunner of the present repeater. The pentode was favored over the triode for this amplifier, for obvious reasons, and in 1936 the triode development was discontinued.

Early in the development of the tube, three basic assumptions were made. These were: 1. that operation at the lowest practical cathode temperature would result in the longest thermionic life, 2. that operating plate and screen voltages should be kept low, and 3. that the cathode current density should be kept as low as was practicable.

The first assumption, concerning the cathode temperature, was based on the observation of life tests on other types of tubes. While the data at the time of the decision were not conclusive, there was definite indication that too high a cathode temperature shortened thermionic life. Little was known about life performance in the temperature range below the values conventionally used.

The second assumption, concerning low screen and plate voltages, had not been supported by any experimental work available at the time of decision. Sixty volts were originally considered for the output stage; this value was later lowered when other operating conditions were changed. Subsequent results showed that in this range the voltage effects on thermionic life were relatively negligible.

The third assumption, that low-cathode current density favored longer thermionic life, affected the tube design by suggesting the use of a large, coated, cathode area. This implied the use of relatively high cathode power. It was decided, early in the planning of the repeater, that the voltage drop across the three heaters operated in series would be used to supply part or all of the operating plate and screen potentials. For a 60-volt plate and screen supply, the heater voltage could be as high as 20 volts. A quarter of an ampere was considered a reasonable cable current and consistent with voltage limitations at the cable terminals. Thus 5.0 watts were available for each cathode. With this power, a coated area of 2.7 square cm (centimeters) was provided. The value of the cathode current, the cathode area, and the interelectrode spacings define the transconductance. Very liberal interelectrode spacings were provided, consistent with reasonable tube performance. The original design called for a spacing of 0.040 inch between control grid and cathode. This value was later reduced to 0.024 inch, and a satisfactory design was produced which gave 1,000 micromhos or one ma (milliampere) per volt at a cathode current drain of approximately 2.0 ma. The resulting current density of approximately 0.7 ma per square centimeter is in sharp contrast with values such as 50 ma per square cm, used currently in tubes designed for the more conventional communication uses. Subsequent data, discussed later, indicate that for current densities of a few milliamperes per square centimeter, the exact value is not critical in its effect on thermionic life.

SUBSEQUENT PRODUCTION PROGRAMS

The development of the tube was pursued on an active basis through the years leading up to World War II. During the war, development activity essentially stopped. It was possible to keep only the life tests in operation. After the war the development of the tube was completed and a small production line was set up in Bell Telephone Laboratories, under the direct supervision of the tube development engineers, to make and select tubes for a cable between Key West, Fla., and Havana, Cuba.

This cable turned out to be a "field trial" for the transatlantic cable which was to come later. A total of six submerged repeaters containing 18 tubes was laid and the cable put in operation in June 1950. The cable has been in operation since this date without tube failure, and periodic observations of repeater performance indicate no statistically significant change in tube performance over the 6 years of operation.

Sufficient tubes were made, at the same time as the Key West-Havana run, for a future transatlantic cable. These tubes were never used, principally because they had been assembled with tin-plated leads. Tin plating, subsequent to the laying of the Key West-Havana cable, was found capable of growing "whiskers."[1]

In 1953, another production setup in Bell Telephone Laboratories was established for the fabrication of tubes for the Newfoundland-Scotland section of the transatlantic cable. On the completion of this job fabrication was continued in order to provide tubes for an Alaskan cable between Port Angeles, Wash., and Ketchikan, Alaska. After a pause of several months another run was made to provide tubes for a cable to be laid between California and the Hawaiian Islands.

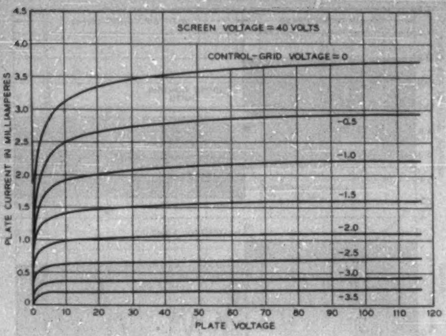

Fig. 5. Typical plate voltage-plate current characteristics for type 175HQ tube

Mechanical Features

The tube, shown on the left in Fig. 1, is supported in the repeater housing by two soft-rubber bushings into which the projections of the two ceramic end caps fit. All leads are flexible and made of stranded beryllium copper which has been gold-plated before braiding. Both for convenience in wiring in the circuit and for holding down the control-grid to anode capacitance, the grid lead has been brought through the opposite end of the tube from the other leads.

A number of somewhat unusual constructional features appear in the tube. The stem on which the internal structure is supported consists of a molded glass dish into which seven 2-piece beaded dumet leads are sealed. The parts used in a stem, and also a finished stem, are shown in Fig. 2. It is usual to embed the weld or "knot" between the dumet and nickel portions of the lead in the glass seal to provide more structural stiffness. This has not been done in this stem because it was believed that a fracture of a lead at the weld could be detected more easily if it were not supported by the seal. It might be questioned why the modern alloys and flat stem structure have not been used but it is to be remembered that one gas leak along a stem lead would disable the system. Experience gained with the older materials provides greater assurance of satisfactory seals.

The structure of the heater and cathode assembly is unique, as may be seen in Fig. 3. A heater insulator of aluminum oxide is extruded with seven holes arranged as shown. This insulator is supported by an 0.025-inch molybdenum rod inserted in the center hole. The heater, consisting of about 36 inches of 0.003-inch tungsten, is wound into a helix having an outside diameter of 0.013 inch. After dip coating by well-known techniques the heater is threaded through the six outer holes in the insulator. A suspension of aluminum oxide is then injected into the holes in the insulator so that on final firing the heater becomes completely embedded. The cathode sleeve, which is necked down at one end, as shown in Fig. 3, is slipped over the heater assembly and welded to the central molybdenum rod which becomes the cathode lead. By this means is obtained a uniform temperature from end to end of the cathode. Under normal operating conditions the heater temperature is approximately 1,100 C (degrees centigrade), which is considerably under the temperature found in other tubes.

Connection of the heater to the leads from the stem presented a serious design problem. Crystallization of tungsten during and after welding and mechanical strains developed by thermal expansion frequently are the causes of heater breakage. This problem was successfully overcome by the means illustrated in Fig. 4. Short sections of nickel tubing are slipped over the cleaned ends of the heater coil, and matching pieces of nickel wire are inserted as cores. These parts are held together by tack welds at the mid-points of the tubing. The heater stem leads are bent, flattened, and formed to receive the ends of the heater, which are then fastened by welds as indicated in the drawing.

A serious attempt has been made in the design of the tube to hold the number of fastenings that depend entirely on one weld to an absolute minimum. The grids are of conventional form in which the lateral wires are swaged into notches cut in the side rods or support wires. The side rods as well as the lateral wire are molybdenum. This produces grids which are considerably stronger than those for which more conventional materials are used.

The upper mica is designed to contact the bulb, and the bulb is sized accurately to receive and hold the mica firmly. The tube in its mounting will withstand a single 500*g* (gravitational acceleration) 1-millisecond shock without apparent changes in mechanical structure or electrical characteristics. It is estimated from preliminary laying tests that accidental or unusual handling would rarely result in shocks exceeding 100*g*.

Electrical Characteristics and Life

The average operating electrical characteristics for the *175HQ* tube are given in Table I, and a family of plate-voltage versus plate-current curves for a typical tube is given in Fig. 5, for a region approximating the operating conditions.

The development of a long-life tube offers good opportunities to observe effects that are likely to be missed where shorter lives are satisfactory. For example, some of the earliest tubes made, after 20,000 hours on the life racks, began to show a metallic deposit on the bulbs. Immediate concern for the lowering of insulation resistance across mica spacers prompted an investigation. The source of the trouble was traced to the use of plates made from a grade of nickel which allowed magnesium as a contaminant to evaporate. A change was made to molybdenum, and this has been employed successfully since that experience.

The effect on the thermionic life of operating at different cathode current densities was of interest. Life tests were started in which the cathode current drain in one group of tubes was approximately 7.5 ma (2.8 ma per cm^2) and in another group the average cathode current was 0.6 ma (0.2 ma per cm^2). The test results presented in Fig. 6 after 120,000 hours, or the equivalent of approximately 14 years, show that at the cathode temperature of approximately 710 C* selected for the test, there is practically no current density effect in this 12-to-1 current range. The circles indicate average values, while the dots and crosses at each test point show the positions of the extreme tubes of the group.

Similar life tests, set up to show the effect of operating at plate and screen voltages of 60 volts as compared to 40 volts, indicate no essential differences in performance after 8 years of operation.

The cathode temperature is one of the most critical operating variables affecting thermionic life. As already mentioned, the early development objective was a cathode power 5.0 watts which corresponded to 710 C for the cathode design used at that time. The results of operating at this condition are illustrated in Fig. 7. No tubes have been lost from the test where the direct cause has been failure of emission. Several tubes were lost because of mechanical failure resulting from design defects which were subsequently corrected. It will be observed that at the end of 17 years the average transconductance is 80% of its original value, and the poorest tube has dropped to 69%. There is

* All cathode temperatures referred to in this paper are "true" temperatures, not uncorrected pyrometer temperatures.

Table I. Average Operating Electrical Characteristics for the 175HQ Tubes

	Stages 1 and 2	Stage 3
Heater Current	220	217 milliamperes
Heater Voltage	18.2	18.4 volts
Heater Power	4.0	4.0 watts
Control-Grid Bias	−1.3	−1.4 volts
Screen Voltage	38	40 volts
Plate Voltage	32	51 volts
Screen Current	0.3	0.3 milliamperes
Plate Current	1.3	1.4 milliamperes
Transconductance	980	1,010 micromhos

	All Stages
Capacitances (cold, with shield)	
Input Capacitance	9.2 μμf
Output Capacitance	15.6 μμf
Plate to Control-Grid Capacitance	0.03 μμf

Table II. Typical Analysis of Inco 220 Nickel Cathode Melt 84

Analysis Made Prior to Hydrogen Firing

Impurity	Per Cent	Impurity	Per Cent
Aluminum	0.008	Manganese	0.11
Boron	<0.004	Silicon	0.033
Cobalt	0.46	Titanium	0.032
Chromium	<0.005	Oxygen	0.0001
Copper	0.028	Sulphur	0.0016
Iron	0.093	Carbon	0.058
Magnesium	0.046		

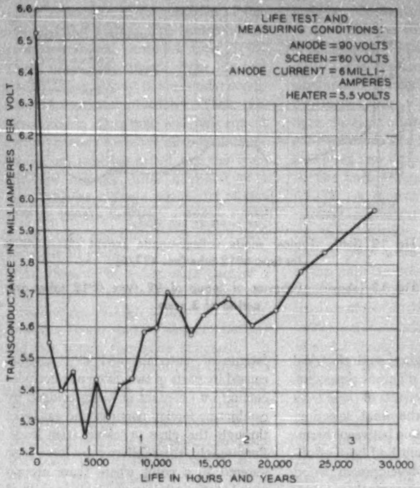

Fig. 10 (left). Behavior of group of 50 tubes deliberately left with "gas generator" (tube type 6P12)

reason to believe that test-set difficulties may very well account for a large part of the variation shown in the first 3 years.

The cathode coatings used in all experimental and final tubes for the Newfoundland-Scotland link of the transatlantic cable are the conventional double-carbonate coatings. The cathode base material is an International Nickel *220* nickel. The particular melt used for the transatlantic cable is known as melt *84*. A typical analysis for melt-*84* nickel cathodes is given in Table II.

The relatively high carbon content (0.058%) of melt *84*-cathode nickel is capable of producing excessive reduction of barium in the cathode coating.[2,3] A treatment in wet hydrogen prior to coating, at 925 C for 15 minutes, reduces the carbon in the cathode sleeve to about 0.013%.

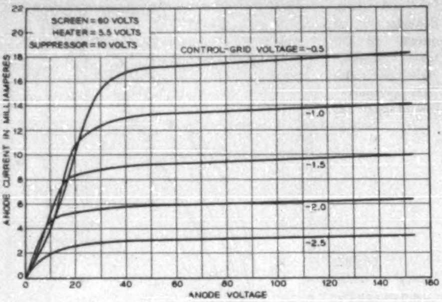
Melt *84* was as close in composition as was obtainable to melts *60* and *63*, previously used for the Key West–Havana tubes. The results of up to 5 years of life testing were thus available on materials of very similar composition.

One common cause of tube deterioration with life is the result of formation of an interface layer on the surface of the cathode sleeve. It is known that the rate of development of this layer depends in a complex way on the chemical composition of the nickel cathode core material. The effect of such a layer is to introduce a resistance in series with the cathode. This results in negative feedback and reduces the effective transconductance. Since the effect of a given feedback resistance in this location is proportional to transconductance, the relatively low value for the *175HQ* tube tends to minimize this feedback effect. In addition, the low cathode temperature tends to reduce the rate of formation of interface resistance, and the relatively large cathode area tends further to minimize the effects. The final decision to use melt *84* was based on accelerated aging tests which showed it to be superior to melts *60* and *63* from an interface standpoint. (The interface problem will be discussed further in a later section.)

As the development of the tube proceeded, both the processing of the parts and the cleanliness of the mount assembly were improved, and the cathode emission level increased. Life tests indicated that better thermionic life might be obtained by operating at a lower cathode temperature. Accordingly, a cathode power of approximately 4.0 watts was adopted, which corresponds to a temperature of 670 C. A life test, now 45,000 hours, or about 5 years old, shows the results (see Fig. 8) of operating groups of tubes at three different cathode temperatures. This is a well-controlled test in that the tubes for the three groups were picked from tubes having common parts and identical fabrication histories. It may be noted that the average of the 725 C lot has lost approximately 5% of the initial transconductance, whereas the 4.0-watt group after about 5 years has lost essentially none of its transconductance. The 3.0-watt (615 C) group shows serious instabilities in its performance. In some of the tubes the cathode temperature has not been sufficiently high to provide the required emission levels.

The design of the repeaters in the Newfoundland-Scotland section of the cable is such that reasonably satisfactory cable performance would be experienced if the transconductance in each tube dropped to 65% of its original value. The life test performance data presented in Figs. 7 and 8, and other tests not shown, indicate that operation of the *175HQ* tubes in the transatlantic cable at approximately 4.0 watts will assure satisfactory thermionic performance for well over 20 years.

Mention was made that cleanliness in the assembly of the mounts was a factor which affected thermionic activity. Interesting evidence supporting this view was obtained during the fabrication of tubes for the Key West–Havana cable. The quality control type of chart reproduced in Fig. 9 shows the average change in transconductance between two set values of heater current for the first five tubes in each group of approximately 24 tubes made. The data were taken after 5,000 hours of aging. A sharp improvement in thermionic emission was noted at a point on the chart where about one half of the tubes had been fabricated. An examination of the records (which are very carefully maintained) disclosed that the windows of the assembly room were sealed and air cleaning and conditioning were put in effect at the point indicated on the chart. No other changes in processing or materials occurred at this time. A second definite improvement in therm-



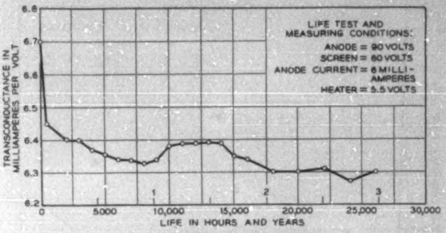


Fig. 12 (left). Typical anode voltage–anode current characteristics for type 6P12 tube (no. 457/6)

Fig. 13 (above). Behavior of group of 92 type 6P12 tubes over period of 3 years

ionic emission occurred when the work was moved from the location in New York City to the new and better controlled environment at Murray Hill, N. J.

Fabrication and Selection

All assembly operators on the *175HQ* tube program wore nylon* smocks to keep down the amount of dust and lint that might otherwise leave their clothing and get into the tubes. Rayon acetate gloves were worn in handling parts as a protection against perspiration. Rubber finger cots did not prove satisfactory because they covered too little area, and once contaminated they did not absorb the contaminant.

The tubes for the Newfoundland-Scotland section of the cable were made at Bell Telephone Laboratories under the extremely close supervision of many of the original development engineers. All materials going into the tubes were carefully checked, and wherever possible they were tried out in tubes. Experience under accelerated aging conditions was obtained before these materials were used. For example, although during the developmental period all glass bulbs were used as received without any failures resulting, less than one quarter of the bulbs bought for the actual cable job passed the inspection requirements. Each batch of heaters was sampled and results were obtained on intermittent and accelerated tests before approval for use.

The fabrication of the tube was carried out with extreme care by operators specially selected for the job. If normal commercial test limits had been applied to the tubes after exhaust, the yield from acceptable mounts would have been about 98% to 99%. Yet only about one out of every seven tubes pumped was finally approved for cable use. All tubes were given 5,000 hours' aging, and electrical tests were made at six different times during this period. The results of these tests weighed heavily in the final selection. For example, a correlation between thermionic life and gas current had been established during the tube development period and only tubes having control-grid currents caused by gas of less than 5×10^{-11} ampere were acceptable. This corresponds to a gas pressure of approximately 2×10^{-7} mm (millimeters) of mercury. Very thorough mechanical inspections were made after the 5,000 hours' aging to ensure that there were no observable mechanical deviations that could cause trouble. The history of each group of 28 tubes, from which prospective candidates for the cable were selected, was reviewed to see if any group abnormalities were found. In case a suspected trait was seen, all tubes in the group were ruled out for cable use.

As an aid in the selection of tubes for the cable, all pertinent data were put on International Business Machine cards. It was then possible to manipulate and present the data in many very helpful ways that would have otherwise been wholly impractical from the standpoints of time and man-power considerations. An over-all total of about half a million bits of information was involved.

Reliability Prospects

Questions are frequently raised concerning the probability of tube failures in the system. There are two categories into which failures naturally fall: catastrophic failures, and failures caused by cumulative effects, such as the decay of thermionic activity, development of primary emission from the control-grid, or the build-up of conductance across mica insulators or glass stems.

The catastrophic failures include open connections caused by weld failures or fatigue of materials, and short circuits caused by parts of two different electrodes coming into contact or being bridged by conducting foreign particles and gas leaks through the glass or along stem leads. Fortunately, these failure rates have been lowered to a point where there are no sound statistical data available in spite of the substantial amount of life testing that has been done. In approximately 4,800 tubes made to date, there have been four failures that were not anticipated by the inspection made. The four failures were of different types, and occurred either at or before 5,000 hours of life. All four were of types more likely to occur during the early hours of aging and handling.

Among the cumulative types of failure, life testing has indicated no apparent problem with either the growth of insulation conductance or primary emission from the grids. As indicated earlier in the paper, thermionic life results are such that there is reason for optimism that no failures will occur in 20 years.

Tubes for the Nova Scotia–Newfoundland Cable

Trend of Tube Development in British Submarine Repeater Systems

Early Use of Commercial Receiving Tubes

The development of submerged telephone repeaters in Britain has taken a somewhat different course from that followed in the United States. Off North America, deep seas are encountered as soon as the continental shelf has been passed. Consequently, emphasis has been placed from the beginning on the design of repeaters for ocean depths. In Britain, separated from many countries by only shallow seas, it was natural to start with a repeater specially designed for shallow water. Such a repeater was laid in 1944 in an Anglo-Irish cable.

---

* Trade name for DuPont polymide fiber.

The tubes used in the amplifier of this repeater were normal, high-transconductance, commercial pentodes, type *SP61*. These tubes were known, from life test results, to last at least 2 years under conditions of continuous loading. Their performance in the first and subsequent early repeaters exceeded all expectations. So far, one tube has failed, and this from envelope fracture, after a period of 4 years' service. There remain 23 of this type on the sea bed with a service life of 5 or 6 years, and three tubes which have survived 10 years.

All these *SP61* tubes were part of a single batch made in 1942. Their performance set a high standard; it was, however, found that subsequent batches did not attain the same standard. In 1946 therefore the British Post Office was faced with the fact that future development of the shallow-water system of submerged repeaters was dependent on the production of a tube type which could take the place of the 1942 batch of *SP61* tubes. This situation led to the formation of a team at Dollis Hill whose terms of reference were, specifically, to produce the replacement tube and, generally, to study the problems presented by the use of tubes in submerged repeaters. Apart from changes in the specific requirements, these terms of reference have remained unchanged from that day to this.

Replacement by the G.P.O. 6P10 Type

Coincident with the rapid exhausting of stocks of satisfactory *SP61* tubes for submerged telephone systems, there arose the need for a tube type for a submerged telegraph repeater. This latter requirement was complicated by the fact that the telegraph cable was subject to severe overall voltage restrictions which precluded the 630-ma heater current required for the 4-watt cathode of the *SP61*. To avoid production of one tube type for telephone systems and another for telegraph, it was decided that the replacement for the *SP61* should have a 2-watt cathode with a 300-ma heater.

During 1944 and 1945, a very successful, miniature, high-slope pentode, the *CV138*, was produced for the armed services. Its electrical characteristics were superior to those of the *SP61* and, in addition, it used a 2-watt cathode. It was therefore decided to base the replacement tubes, electrically, on the *CV138*, while at the same time retaining freedom to amend the mechanical features in any way which might seem to favor the specific requirements of submerged repeater usage: in particular, maintenance of the level of transconductance unchanged for long periods. Consequently, three major mechanical changes were made at the outset of the project. The miniature bulb of the *CV138* was replaced by one of normal size (approximately 1 inch in diameter and $2^1/_2$ inches long). This was done to reduce the glass temperature and so reduce gas evolution. At the same time, a normal press and drop seal were substituted for the button base and ring seal of the *CV138*, as it was felt that, with the techniques available, the former would be the more reliable. With the use of a normal press there immediately followed a top cap control-grid connection, and thus was produced a double-ended tube in place of the single-ended *CV138*.

These three modifications and a number of major changes to improve welding and assembly techniques led to the General Post Office type known as the *6P10* (a pentode *P* with a 6.3-volt heater *6* of design mark *10*). The *6P10* replaced the *SP61* in the 18 shallow-water repeaters laid in various cables after 1951. There are therefore 54 type *6P10* tubes in service on the sea bed with periods of continuous loading ranging from 2 to 4 years. There has been one failure due to a fractured cathode tape, and one other repeater was withdrawn from service to investigate a high-frequency oscillation associated with a tube. The oscillation cleared, however, before the cause could be identified.

The first 18 of the *6P10*-type tubes used in repeaters had conventional nickel cathode cores. Appreciation of the problem of interface resistance led to the use of platinum as a core material for the following 36 tubes. The steps leading to this radical change of technique will be described later.

Development of the 6P12 for Long-Haul Systems

Although submerged-repeater development started naturally in Britain with shallow-water systems, it was inevitable that attention should ultimately turn towards transoceanic cables. The tube requirements for such long-haul systems differ from those for short-haul shallow-water schemes, in that operation at a lower anode voltage is essential. A new tube to replace the *6P10* was therefore unavoidable.

By the time emphasis started to shift in Britain from shallow-water to deep-sea systems, considerable experience had been gained at Dollis Hill on the production techniques required to fit a *6P10*-type tube having a platinum cathode core for submerged-repeater usage. When it became apparent that a new tube had to be designed for the first long-haul system, it was resolved to retain as much as possible of the *6P10* structure in order to take full advantage of familiar techniques. The *6P10* was therefore redesigned for 60-volt operation simply by a major adjustment to the screen-grid position and minor alterations elsewhere. The new tube became known as the *6P12*, and was used in seven repeaters installed in the Aberdeen-Bergen cable. This scheme was regarded as a proving trial for the Newfoundland–Nova Scotia section of the transatlantic project.

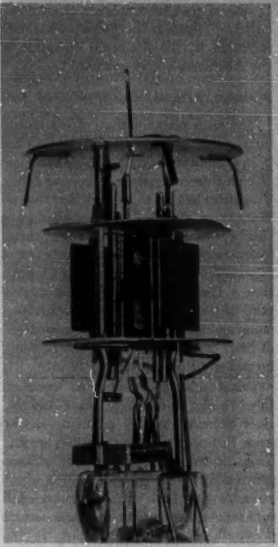

Fig. 14. Interior of 6P12-type tube

It has always been appreciated that the use of high-transconductance tubes using closely spaced electrodes will involve a higher liability to mechanical failure by internal short circuits. Practical experience in shallow-water schemes, where repeater recovery is a comparatively cheap and simple operation, seems to show, however, that such risks are outweighed by the economic advantage of a tube capable of wider frequency coverage. In point of fact, a failure by internal short circuit has not yet occurred on any shallow water system.

This background of experience explains the British choice of a high-transconductance tube for deep-sea systems, but the greater liability to mechanical failure by use of parallel amplifiers is acknowledged. Confidence in this policy has been increased by the successful operation of the Aberdeen-Bergen system.

Problems of Development of the 6P12 Tube

The main preoccupation of the thermionics group at Dollis Hill since 1946 has been a study of the electrical life processes of high-transconductance receiving tubes. This effort has led to a conviction that all changes of electrical performance have their origin in chemical or electrochemical actions occurring in the tube on a micromicro or millimicro scale of magnitude. The form of change most important to the repeater engineer is decay of transconductance; this will be considered in brief detail as typical of the developmental effort put into the *6P12* tube.

Transconductance decay in common tubes results from two separate and distinct chemical actions occurring in the oxide cathode itself. Both actions are side issues, in no way essential to the basic functioning of the cathode, and it seems probable that both can be eliminated if sufficient understanding of their nature is available. The first action is the growth of a resistive interface layer between the oxide matrix and its supporting nickel core (discussed briefly in an earlier section). This effect is assumed to be due to silicon contamination of the nickel core metal, as follows:

$$BaO + Si = Ba_2SiO_4 + 2\ Ba$$

The resistance of the layer of barium orthosilicate rises as it loses its barium activator and approaches the intrinsic state. The effect of the interface resistance is to bring negative feedback to bear on the tube with resulting loss of transconductance. The second deleterious action is loss of electron emission from the oxide cathode by direct destruction of its essential excess barium metal by oxidizing action of residual gases. Such gases result from an imperfect processing technology.

These two problems have been approached in the *6P12* tube in a somewhat novel manner. The conventional nickel core is replaced by platinum of such high purity (99.999%) that the possibility of appreciable interface growth from impurities can be disregarded. The only factor to be considered is the appearance of high-resistive products of a possible interaction between platinum and the alkaline earth oxides. Batch tests over a period of 30,000 hours have failed to show any sign whatever of such an action occurring, and workers at Dollis Hill now regard the pure platinum-cored tube as free from the interface resistance phenomenon.

The problem of avoiding gas deactivation of the cathode is a more difficult one and so far has been reduced rather than eliminated. It is now appreciated that the dangerous condition arises from "gas generators" left in the tube, and not from a true form of residual gas pressure after seal-off from the pump. These gas generators are solid components of the tube which give off a continual stream of gas over a prolonged period of time. The gas evolution rates are usually so small that they cannot be detected by reverse-grid current measurement, but they tend to integrate gas by absorption on the cathode and to destroy its activity. The gas generators are usually of finite magnitude and, depending mainly on diffusion phenomena, evolve gas at a rate which falls in roughly exponential fashion with time. The probability of transconductance failure is therefore highest in early life and tends to lessen as the generators move to exhaustion.

One particularly useful feature of the platinum-cored cathode is its freedom from core oxidation during gas attack, which leaves the tube free to recover from transconductance failure when the gas attack has passed. Fig. 10 shows the behavior of a group of 50 tubes which have been deliberately left in possession of a component capable of generating carbon monoxide over a prolonged period. The curve shows the characteristic recovery of a platinum-cored oxide cathode, with the gradual passing of what is thought to be a typical gas attack.

One problem that has attracted much attention at Dollis Hill is the actual manner in which a platinum-cored cathode recovers from a gas attack. The mechanism must involve the dissociation of a small fraction of the oxide cathode itself, with the retention of barium metal in the oxide lattice, and the evolution of oxygen. That such an essential mechanism does in fact exist has been proved by the slow accumulation of barium metal in the platinum core. This accumulation takes the form of a distinctive alloy of barium and platinum, and occurs only when the cathode is passing current. The barium regenerative process therefore seems to be electrolytic in nature and, depending only on current flow and a stock of oxide, would appear to be virtually inexhaustible.

These few remarks are perhaps sufficient to give some idea of the lines on which the British research effort has run during the past decade. More detailed descriptions have already been presented elsewhere.[4–7]

ELECTRICAL AND MECHANICAL CHARACTERISTICS

Electrical Characteristics

The main electrical characteristics of the *6P12* are shown in Figs. 11 and 12. The heater voltage used for both sets of curves is 5.5 volts, the same value as that used in the British amplifier.

Fig. 11 shows the change of transconductance with anode current, with screen voltage as parameter. An anode voltage of 40 volts and a suppressor voltage of zero correspond with the static operating conditions in the first two stages of both the Aberdeen-Bergen and the British T.A.T. (transatlantic telephone) amplifiers. The screen voltage and anode current of the first two stages of the British T.A.T. amplifier were chosen to be 40 volts and 3 ma respectively.

Fig. 12 shows the normal anode voltage–anode current characteristics for conditions corresponding to the output stage of the amplifier (static operating point, anode voltage = 90, screen voltage = 60, anode current = 6 ma). A final electrical characteristic worthy of comment is the level of reverse-grid current. For all specimens tested at the time of selection, after about 4,000 hours' life test the level is very low, about 100 micromicroamperes per milliampere of anode current.

Life Performance

The life performance of the *6P12* is still a matter for conjecture. The only concrete evidence available is the behavior of a group of 92 tubes placed on life test some 3 years ago. The change of the average transconductance of this group (with anode current constant at 5 ma) is shown in Fig. 13. It may be well appreciated that there is no definite trend over the past year which permits any firm prediction of life expectancy. Examination of other tube characteristics is equally unproductive from the point of view of prediction of failure.

In the early stages of the test there were eight mechanical failures. The cause in all instances was identified and corrected in subsequent production before the start of the T.A.T. project.

Mechanical Characteristics

The chief mechanical characteristics of the *6P12* have been referred to as very similar to those of the *6P10*. A photograph of the interior of the tube is shown in Fig. 14.

TUBE SELECTION TECHNIQUES

Not all the tubes that were found after production to be potentially suitable for

Vol.
Pt. 1
195

the British T.A.T. amplifier, remained equally suitable after the life test period of about 4,000 hours. A brief account of how the best were selected follows.

The fact that every tube had to pass conventional static specification limits needs little emphasis here. This test was, however, supplemented with three additional types of specification. First, every tube was tested in a functional circuit, simulating that stage of the amplifier for which the tube was ultimately intended. Here measurements were made of shot noise (appropriate to first-stage usage), and harmonic generation (appropriate to the output stage), in addition to the usual measurements of transconductance, anode impedance, and working point.

Second, all tubes were subject to intensive visual scrutiny in which some 80 specific constructional details were checked for possible faulty assembly.

Third, the life characteristics of transconductance, total emission and working point were examined over the test period of about 4,000 hours for unsatisfactory trends. Although this type of specification is more difficult to define precisely, its application is probably more rigorous and exacting than any of the previous specifications.

Only if a tube passed the conventional test and the three supplementary tests was it considered adequate for inclusion in a repeater.

Conclusions

The laying of the present repeatered transatlantic cable represents by far the most ambitious use to date of long-life, unattended electron tubes. In this project alone there are 390 tubes operating on the ocean bottom. If to this number are added the ocean bottom tubes from earlier, shorter systems, those used in the Alaskan cable completed a few months ago, and those to be used in the California-Hawaii cable to be laid in 1957, the total number on the ocean bottom will be about 1,000. The capital investment dependent on the satisfactory performance of these tubes is probably about 100 million dollars—strong evidence of faith in the ability to produce reliable and trustworthy tubes.

It is of interest to note that the two groups working on the tubes on opposite sides of the Atlantic had no intimate knowledge of each other's work until after the tube designs had been well established. As a result of subsequent discussions, it has been surprising and gratifying to find how similarly the two groups look at the problems of reliability of tubes for submarine cables.

The authors would be completely remiss if they did not mention the contributions of others in the work just described. These projects would have been impossible had it not been for the enthusiastic, cooperative and careful efforts of many people working in varied fields. Over the years chemists, physicists, electrical and mechanical engineers, laboratory aides, shop supervisors, and operators all have made essential contribution to the projects. It would be impractical and unfair to attempt to single out for mention the work of specific individuals whose contributions are outstanding. These are too many.

Cable Design and Manufacture for the Transatlantic Submarine Cable System

A. W. LEBERT H. B. FISCHER M. C. BISKEBORN

Synopsis: The transatlantic cable project required that two repeatered cables be laid in the deep-water crossing between Newfoundland and Scotland, and one across the shallower waters of Cabot Strait. The same structure was adopted for the cables laid in the two locations.

This paper discusses the considerations leading to design of the cable and describes the method of manufacture, the means and equipment for control of cable quality, the process and final inspection procedures, the electrical characteristics of the cable, and factors relating to mechanical and electrical reliability of the final product.

Description of Cable

GENERAL features of the cable structure adopted for the transatlantic cable project[1] are illustrated in Fig. 1. The cable consists of two basic parts: 1. the coaxial, or the electrical transmission path, and 2. the armor or outer protection and strength members.

The coaxial is made up of three parts: 1. the central conductor, 2. the insulation, and 3. the outer or return conductor. The central conductor is composed of a copper center wire surrounded by three helically applied copper tapes. The insulation is a polyethylene compound which is extruded tightly over the central conductor. The insulated central conductor is called the cable core. The outer or return conductor is composed of six copper tapes applied helically over the insulation.

The protection and strength components shown in Fig. 1 for the type *D* deep-water cable are provided by a teredo tape of thin copper applied over the outer coaxial conductor, a fabric tape binding, a layer of jute rove for armor bedding, the textile-covered armor wires and, finally, two layers of jute yarn flooded with an asphaltum-tar compound. This type of cable is characterized by the extra tensile strength of its armor wires and the precautions taken to minimize their corrosion.

A Conference Paper presented at the Symposium on the Transatlantic Submarine Telephone Cable, during the AIEE Winter General Meeting, New York, N. Y., January 21–25, 1957.

A. W. Lebert, H. B. Fischer, and M. C. Biskeborn are with Bell Telephone Laboratories, Murray Hill, N. J.

The authors wish to acknowledge the many contributions made by the members of the staff of the Simplex Wire and Cable Company, Submarine Cables Limited, the British Post Office, and the Bell Laboratories groups involved during the course of the design and manufacture of the transatlantic cable.

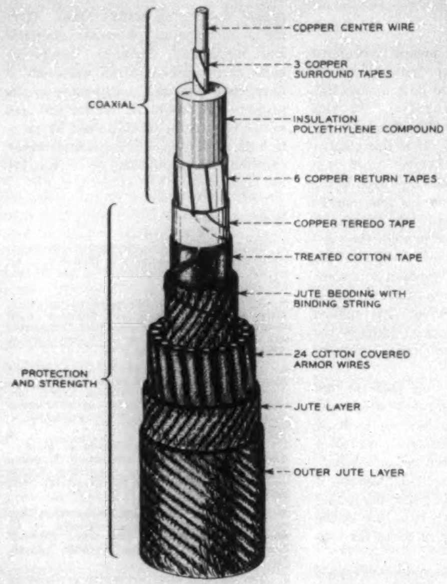

Fig. 1. Structural features of deep-water type of cable

At the shallow-water shore ends, the armor types are characterized by the use of mild steel wires which are increased in diameter in steps as the landing is approached. These types are designated *A* and *B* and will be described in greater detail later.

The transmission loss of this cable structure at the top operating frequency of 164 kc is 1.6 db (decibels) per nautical mile and is 0.6 db per nautical mile at 20 kc, which is the lower end of the frequency band. The high-frequency impedance of the cable is about 54 ohms.

Basis of Design

A coaxial structure was first used for telephone and telegraph service in a submarine installation in 1921, between Key West and Havana, Cuba. Three coaxial cables with continuous magnetic loading and no submerged repeaters were laid. One telephone circuit and two telegraph circuits were provided in each cable for each direction of transmission.

In 1950, a pair of submarine coaxial cables,[2] which included flexible submerged repeaters, was laid between Key West and Havana, Cuba. Each cable furnished 24-voice circuits. One cable served as the "go" and the other as the "return" for the telephone conversations. The transatlantic telephone cable design is similar to this cable except that the nominal diameter of the insulation is 0.620 inch instead of 0.460. An outstanding difference between the transatlantic and Key West–Havana systems is cable length, about 2,000 nautical miles as compared with 125. This difference influenced significantly the permissible electrical and mechanical tolerances applying to the cable structure.

The installation of some 1,200 miles of cable with island-based repeaters for a communication and data transmission system for the U. S. Air Force, between Florida and Puerto Rico,[3] followed the 1950 submarine cable system. The design of this cable is identical with that of the transatlantic cable, except for differences in the permissible dimensional tolerances on the components of the electrical transmission path. Data obtained on the electrical performance of the Air Force cable provided the transmission characteristic to which the repeaters for the transatlantic project were designed.

The design of these cable installations were the result of many years of cable development effort, which was guided by the successes and failures of the earlier submarine telegraph cables. The 1950 Key West–Havana and the Air Force cables differed from the earlier structures in one important respect, namely, the lay of the major components. A series of fundamental design studies during the 1930's and 1940's and extensive field tests in the Bahamas in 1948 demonstrated that having the same direction of lay of the major components of a cable was very important in minimizing kinking and knuckling. In addition, other laboratory tests pointed the direction for the adoption of new materials and techniques in the manufacture of these cables. These and subsequent improvements in materials and manufacturing techniques were included in the transatlantic cable design.

Since the electrical characteristics of a cable have a direct bearing on the over-all system design and performance, considerable emphasis was placed on this phase of the design of the transatlantic cable. The size of central conductor and core used in the Air Force cable resulted in low unit attenuation and low d-c resistance. These advantages resulted in the adoption of this size of cable. However, the outside diameter of the core and the diameter of the central conductor of the coaxial do not fulfill the requirements generally described as optimum for minimum attenuation. Mathematical analysis shows that there is a preferred diameter ratio which results in minimum transmission loss. For the 0.620-inch core diameter employed in the Air Force cable, the central conductor diameter chosen was smaller than the ideal central conductor required to satisfy the preferred diameter ratio. The diameter chosen retained the central conductor size which the Key West–Havana and Air Force cables had proved to be satisfactory from a manufacturing standpoint. The choice was also compatible with the d-c resistance requirement for transmission of power over the cable to each of the repeaters.

While production of the cable was proceeding, cable manufactured to the transatlantic specification was tested near Gibraltar in March 1955. These tests provided a final evaluation of the mechanical and electrical characteristics of this cable before the actual laying of the transatlantic link.

Fig. 2. Design details of types of transatlantic telephone cable for different depths of water

central conductor was chosen to provide a conductive bridge across a possible break in any one of its elements, due to a hidden defect, such as an inclusion of foreign material in the copper. The dimensions of the components of the central conductor were precisely controlled, and a light draw through a precision die was used to compact and size the assembly.

Use of high molecular weight polyethylene (grade 0.3) for core insulation is a major departure from the materials used in early submarine telephone and telegraph cables. The development of synthetic polymers such as polyethylene had led to the replacement of gutta percha as cable insulation, since polyethylene possesses better dielectric properties and mechanical characteristics and is lighter in weight.

Ordinary polyethylene of low molecular weight is subject to environmental cracking, especially in the presence of soaps, detergents, and certain oils. Material of high molecular weight is much less subject to cracking, and by adding 5% (per cent) butyl rubber, further crack resistance is obtained.

Six copper tapes applied helically over the core comprised the return conductor and thus completed the coaxial structure. The dimensions of these tapes were precisely controlled. The helical structure was chosen to impart flexibility to the coaxial.

Insulation of some of the early submarine telegraph cables suffered from attack by marine borers such as the teredo, pholads, and limnoria. To protect against such attack, a thin metallic tape was placed over the insulation in the early submarine cables. The necessity for such protection for the transatlantic cables, especially in deep water, may be questioned, but the moderate cost of this protection was considered cheap insurance against trouble. The copper teredo tape was applied directly over the return conductor, as a helical serving with overlapped edges to completely seal the coaxial from attack by all but the smallest marine organisms.

A cotton tape treated with rubber and asphaltum-tar compound was applied over the teredo tape to impart mechanical stability to the coaxial during manufacture. A small gap between adjacent turns of the helix was specified to permit ready access of water to the return tape structure and to the surface of the core. The use of a gap was based on laboratory tests which showed that transmission loss was dependent to a modest extent on thorough wetting of the exterior of the coaxial. Since transmission loss measurements are made on repeater sections of cable shortly after manufacture to determine whether any length adjustments are required, it was essential that the wetting action be as rapid as possible.

The design of the protection and strength components of the cable was modified according to the depth of the water in which the cable was to be laid. To prevent damage to the coaxial by any cutting action of the armor wires during manufacture and laying, a resilient cushion of jute roving was placed between the armor wires and coaxial. For type *D* cable, a single layer of jute was used; for types *A* and *B*, the bedding was made up of two layers of jute. To protect this jute from microbiological attack, a cutching treatment was employed. The traditional process consists of treating the jute with a vegetable compound called catechu or cutch.

Armor wires were applied over the bedding jute. The use of heavy or intermediate weight near shore has been established by experience with ocean cable. This type of armor is generally

Fig. 3. View of typical manufacturing area for stranding of central conductor

Fig. 4. View of typical manufacturing area for extrusion of core insulation

employed where the cable may be exposed to wave action, bottom currents, rocks, icebergs, ship's anchors, and fishing trawlers. A structure of lighter weight and having higher tensile armor wires is needed in deep water. Table I shows the essential differences between the armor types employed in the transatlantic cable and the approximate range of depths in application.

In addition to these armor types, a shore length of 0.6 nautical mile was provided with an insulated lead sheath under type-*A* armor to facilitate preferred grounding arrangements and to provide signal-to-noise improvement.

Table I

	Armor Wire			
Type	Number of Wires	Diameter, Inches	Material	Application, Fathoms
A	12	0.300	mild steel	up to 350
B	18	0.165	mild steel	350 to 700
D	24	0.086	high-strength steel	greater than 700

Where the tensile strength of the armor wires is most important, as in the type-*D* design, each of the wires was protected against corrosion by a zinc galvanize plus a knitted cotton serving or helically applied tape, the whole assembly being thoroughly saturated with an asphaltum-tar compound. The effectiveness of such protection is clearly apparent when early submarine cables, which used this protection, are recovered and examined. For the heavier armor types, the protection was similar to that of type *D*, except that the textile serving was replaced by a dip treatment to coat each wire with an asphaltic compound.

As the armor wires were applied to each type of cable, additional protection was obtained by flooding the cable with a special asphaltum-tar compound and then applying two layers of jute yarn over the wires. The jute yarn was impregnated with an asphaltum-tar compound before application to the cable and then flooded with another asphaltum-tar compound after application. Formulation of cable flooding materials required the use of compounds having a relatively high coefficient of friction to avoid slippage of the cable on the ship's drum during laying.

To assure satisfactory handling characteristics during the laying operation, all of the metallic elements of the cable were applied with a left-hand direction of lay and the lengths of lay (except for the teredo tape) were chosen so that approximately the same helical length of material was used per unit length of cable. Since the teredo tape was relatively soft and ductile compared to that of the other metallic components, it was not necessary to equate its helical length to that of the other components. Width and lay of the teredo tape were selected to give a smooth, tight covering.

The choice of direction and length of lay of the jute layers was based on experience with cable in factory-handling and laying trials. Experience, particularly with the direction of lay, has shown that improper choice of lays for the two outer layers of jute may result in a cable that is difficult to coil satisfactorily in factory and ship storage tanks. The combination of lays selected for the cable components provided good performance in all the handling operations, including the final laying across the Atlantic.

Manufacture of the Cable

Before considering the manufacture of the cable, it should be understood that the repeater gain characteristic was designed to compensate for the loss characteristic of the cable. Therefore, once this loss characteristic was established, it was essential that all cable manufactured conform with this characteristic.

To obtain the required high degree of conformance, close control had to be kept over all stages of manufacture and over the raw materials. Controls to guide the manufacture of the cable were set up with two broad objectives:

1. To produce a structure capable of meeting stringent transmission requirements.
2. To assure that the manufactured cable could be laid successfully and would not be materially affected by the ocean bottom environment for the expected life of the cable system.

Attainment of a final product capable of meeting the stringent transmission

Fig. 5 (left). Special water tank or pan for tests on immersed cable core

Fig. 6 (right). View of shop for application of cable armor

requirements is described in a later section. Process and raw material controls in manufacture were provided by an inspection team which checked the quality of the various raw materials and the functioning of the several processes during the manufacturing operations. This type of inspection coverage is somewhat unique with submarine cable. It assures the desired final quality by permitting each error or accident to be investigated and corrected on an individual basis.

Cable for the transatlantic crossing was manufactured in the United States by the Simplex Wire and Cable Company and in England by Submarine Cables, Ltd. Differences in machinery and equipment in the plants of the two manufacturers necessitated minor differences in the sequence of the operations and in the processes. The sequence of operations in assembly of the cable was as follows:

Step No.	Operation
1	stranding of central conductor
2	extrusion of insulation
3	runover examination, repair where necessary
4	panning and testing of core
5	jointing of core
6	application of return tapes, teredo tape, fabric tape, jute bedding, and binding string
7	application of armor wire and outer jute layers
8	storage in tanks, testing
9	splicing in repeaters, testing

The only important difference in the sequence of the manufacturing operations at the two plants was the use of separate operations for steps 6 and 7 at Submarine Cables and the combination of these operations in one machine at Simplex.

Other minor differences in process methods related to raw materials. For example, the American supplier purchased polyethylene already compounded with butyl rubber and antioxidant in granule form, ready for use. The British supplier purchased polyethylene, butyl rubber, and antioxidant separately, and performed the compounding in the cable factory.

Stranding of Central Conductor

The central conductor was stranded on a machine which included a revolving carriage with suitable arbors for the three surround tapes. It was equipped with brakes designed to assure equal pay-off tension among the tapes and with detectors to automatically stop the strander in case of a tape break. Each tape was guided through contoured forming rolls to shape the tape to the center wire.

The joints between successive reels of wire and tape used in fabrication of the central conductor were butt brazed. The brazes were staggered to avoid more than one braze in a given cross section of the conductor. The quality of the brazes in these components was controlled by a qualification technique described in the section "Jointing of Core Lengths."

The strand was drawn through several forming dies to size the finished diameter of the central conductor accurately. No lubrication was used because the removal of the resultant residues, which could contaminate the polyethylene insulation, was difficult. The taper in the central conductor diameter due to the die wear was controlled by appropriate replacement of tungsten carbide dies, where used, or by the use of a diamond die where the rate of die wear is less than 1 or 2 micro-inches per mile.

The stranding area in both plants was enclosed and pressurized to guard against dirt and dust settling on the central conductor. A high standard of cleanliness was maintained for parts of the machine which touched the conductor or its components. Undue wear of the guide faces or capstan sheaves was cause for replacement of the sheaves and adjustment of the machine. The stranding area is shown in Fig. 3.

Extrusion of Insulation

To avoid possible contamination of the polyethylene insulating compound in the extruder-hopper loading area, a pressurized enclosure prevented entry of airborne dust and dirt, and the containers of polyethylene compound were cleaned with a vacuum cleaner before being brought into the hopper area. A fine screen pack placed in the extruder reduced the possibility of contamination in the core.

In passing through the extruder, the central conductor was payed off of a large reel with controlled tension, into the pay-out capstan, through an induction heater, through a vacuum chamber, and thence into the cross-head of the extruder. The induction unit heated the central conductor and provided means for controlling the shrinkback of the core insulation and the adhesion of the conductor to the insulation. Shrinkback is a measure of the contained stresses in the insulation.

On the output side of the extruder, the core was cooled in a long sectionalized trough containing progressively cooler water from the input to the output end. The annealing of the polyethylene in the cooling trough also served to hold the shrinkback of the core to a low value. A view of the extrusion shop is shown in Fig. 4.

An important addition to the extrusion operation consisted of the use of an im-

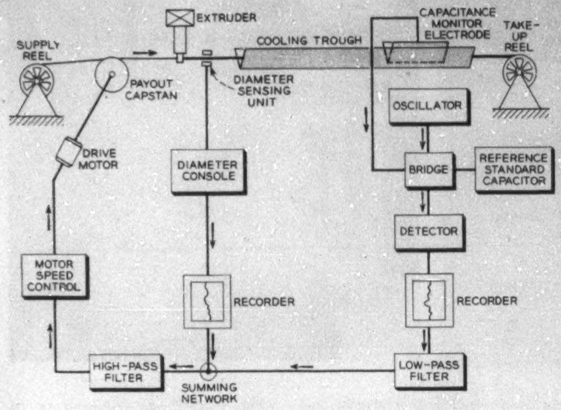

Fig. 7. Simplified block diagram of capacitance monitor servo-control system

proved servo system to control the extruder automatically for attaining constant capacitance per unit length of coaxial. The system used is described in a subsequent section.

Runover Examination

Following extrusion, the core was subjected to continuous visual and tactual examination in a rereeling operation called "runover." The purpose of the runover operation was the detection of inclusions of foreign material in the dielectric and the presence of abnormally large or small core diameters. Core not meeting specification requirements was cut out or repaired.

In addition to visual inspection of the cable, examination of short lengths of core was made at regular intervals with a shielded source of light arranged to illuminate the interior of the dielectric material. Provision of this internal illumination facilitated detection of particles of foreign material well beneath the surface of the core. Strip chart records of the unit-length capacitance of the core obtained during extrusion were used as a guide in searching out regions of uncertainty.

Panning and Testing

After runover, the core was coiled in tanks of water, as shown in Fig. 5. Precautions were taken to remove the air dissolved in the water and thus prevent the formation of bubbles on the surface of the core. The water was also temperature-controlled and circulated to maintain uniform temperature throughout the tank. Thermocouples placed at different levels in the tank determined when the temperature was uniform. Measurements of d-c conductor resistance, a-c capacitance, insulation resistance, and dielectric strength were then made. These measurements are discussed in detail in a later section.

Jointing of Core Lengths

The cable core was manufactured in lengths much shorter than a repeater section, which necessitated connecting the individual core lengths together. Jointing techniques consisted of brazing the central conductor with a V-notch type of junction and of molding in a short section of the polyethylene insulation. After silver-soldering the V-joint, a safety wire consisting of four fine-gauge tinned copper wires was bridged across the junction in an open helix and soft soldered at the ends. Extreme care was taken to remove any excess rosin and to eliminate any sharp points on the ends of the safety wires. The safety wire is intended to maintain continuity of the electrical path in case the braze should fail.

Visual examination of brazes in the actual cable was the only means available for their final inspection. To assure a high degree of quality on these brazes, a system was devised for checking the performance of the operator and the brazing machine initially and at frequent intervals through the use of sample brazes in each of the components, which were tested to destruction. To control the uniformity of brazes, the brazing of the copper wire and tapes was made as automatic as possible by the use of controlled pressure on the components, appropriate-sized wafers of silver solder, and an automatically timed heat cycle. The tests on the brazes used to qualify operators and machinery indicated that a high degree of braze performance was achieved.

Pressure and temperature were carefully controlled during the molding of the insulation over the conductor. Periodic checks similar to those described for brazes were made on operator and molding machine to maintain a satisfactory level of performance. In addition, each molded joint placed in the actual cable was X-rayed and subjected to a high-voltage test while immersed in water.

Application of Return Tapes and Armor Wires

After the core lengths were joined together, they were pulled through the return taping and armoring operations. The machine for applying return tapes was designed specifically for the purpose and was similar in characteristics to the corresponding portion of the strander for the central conductor. Controlled pay-off tension, automatic breakage detectors, precision guides, and contoured forming rolls to shape the tape, were incorporated in the construction.

The return tape, teredo tape, and fabric tape were applied from taping heads, and the bedding jute and binding string were applied from serving heads in a tandem operation. Another set of tandem operations included the application of armor wires, outer jute layers, and the appropriate asphaltum-tar flooding compounds. In the American supplier's plant, both sets of tandem operations were combined into one continuous production line. In the British plant, these operations were divided into two separate production lines. A view of the armoring machine area is shown in Fig. 6. Following the application of the flooding compounds, whiting is applied either at the take-up capstan on the armoring line or in the storage tanks as the cable is coiled.

To avoid core damage, the flow of hot flooding compound was stopped when the cable in the armoring line was stopped. One of the major sources of such stoppages was the reloading of the various applicating heads.

Storage and Testing

In a continous haul-off operation, the cable was conveyed from the armoring machine to the tank house for storage. The cable was coiled in spiral layers, called flakes. Each flake started at the outside rim of the tank and worked toward the central cone. Several 37-nautical-mile repeater sections were stored in each tank.

Water was circulated through the cable tanks to establish uniform temperature conditions throughout the mass of cable. When thermocouples located at appropriate points in the tank indicated that the cable temperature was uniform, measurements were made of attenuation, internal inpedance irregularities, and terminal impedances, d-c resistance, d-c capacitance, insulation resistance, and dielectric strength.

To facilitate these tests without interrupting production, successive repeater section lengths were placed in alternate tanks. By this procedure, a group of four or five sequential repeater section lengths, called an "ocean block," was stored in two tanks. The ends of each repeater section were brought out of the tank to a splicing location. After all tests were completed and the specification requirements met, the repeaters were spliced in. Testing of the ocean block for transmission performance completed the manufacturing operations.

Raw Materials

Stringent requirements were placed on all raw materials used in the manufacture of the transatlantic cable. Detailed specifications covered the basic requirements and the methods of controlling their quality on a sampling inspection procedure. The requirements for the materials were established to ensure that their use would not jeopardize the life of the cable. Since cable life is critically related to the integrity of the insulation, all materials had to be scrutinized for their tendency to cause environmental cracking. These tests were necessarily made on an accelerated basis. Since no correlation exists at present between accelerated tests and long-term (20-year) life tests, only conservative design selections can be justified.

Close tolerance such as ±0.0002 inch for the diameter of the solid center wire in the central conductor were specified for all copper components of the coaxial. In addition, these components had to be free from slag or other inclusions, and the wire drawing and rolling of the tape had to be controlled to assure smooth surfaces, edges of prescribed shape, and freedom from filamentary imperfections. Compounds used in drawing and rolling operations were selected to minimize the possibility of contaminating or causing cracking of the polyethylene. Residual quantities of compound on the wire or tapes were removed prior to annealing, which was controlled to prevent the formation of oxides and to assure clean and bright copper.

The dielectric constant range of the polyethylene-butyl compound was limited to 2.25 to 2.29. These limits were determined by the limited accuracy of the measuring equipment available at the time. Restrictions covered the allowable amount of contamination, since its presence in other than minute quantities might have reduced the dielectric strength or degraded the power factor of the compound.

In addition, the melt index (a factor related to molecular weight) of the final insulating compound composed of polyethylene resin, butyl rubber, and antioxidant was held to 0.15 to 0.50. The melt index of ordinary polyethylene, used for insulation generally, is 2.0 or higher. The low index assured the maximum resistance to environmental cracking.

The cutching and fixing processes used in the manufacture of bedding jute were adjusted to limit the alkalinity of the jute because of the adverse effect of alkaline materials on polyethylene compound. Oils used in the spinning of the jute were selected to obtain types which were not strong cracking agents for polyethylene, and the quantities used were reduced to the workable minimum. The presence of such impurities as bark and roots was restricted to provide the desired fiber strength. The impregnation of the jute was controlled to ensure adequate distribution of the coal tar throughout the fibers without having an excess that would make the jute difficult to handle during the armoring process.

The size, composition, and processing of the armor wires were also placed under close control. Purity, tensile strength, and twist requirements were designed to ensure that the wire could be applied to the cable, and welded, and that it could withstand the expected tensions during laying and pickup. Strength considerations made it mandatory that inclusions of slag or piping of the wire be eliminated. Piping is an unusual condition encountered during rolling or drawing, which results in a hollow shell of steel which may be filled with slag.

Fig. 8. Photograph of capacitance monitor electrode and servo-controller console in laboratory setup

Control of Transmission Characteristics

From a broad point of view, the attainment of a final product capable of meeting the stringent transmission requirements was achieved by the following basic steps.

1. Precision control of the dimensions of the copper conductors, including the diameter of the fabricated central conductor.

2. Automatic control of the insulating process to maintain a constant capacitance, thus compensating for deviations in central conductor diameter and dielectric constant of the insulation.

3. Factory process control, by means of a running average of the measured attenuation characteristic of current production, to guide the adjustment of suitable parameters when necessary.

As indicated in the sections concerning the method of manufacture and the control of raw materials, precautions were taken to obtain a central conductor that had predictable electrical performance, and a controlled taper in over-all diameter along its length. The need for such effort is explained by consideration of the factors that determine the attenuation of a coaxial structure.

The attenuation α of the cable is directly proportional to the a-c resistance R and inversely proportional to the characteristic impedance Z_0 as a satisfactory approximation, i.e.

$$\alpha = \frac{aR}{Z_0}\ db/nm$$

where a is coefficient depending on the units. It is thus clear that control of α may be attained by control of R and Z_0. Since the resistance is a function largely of the diameter of the central conductor, and since it is held to close tolerances, the constancy of impedance completes the requirement for attenuation control.

The characteristic impedance of a transmission line is determined by the following:

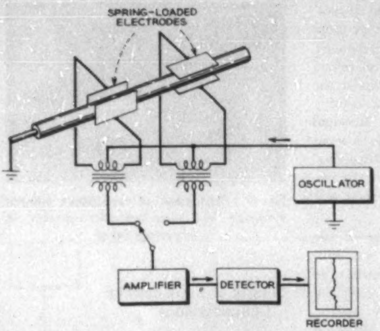

Fig. 9. Simplified block diagram of concentricity gauge for continuous measurement of centering of central conductor

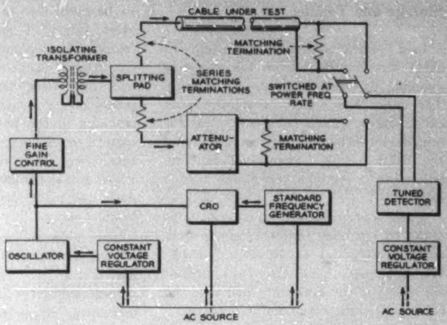

Fig. 10. Simplified block diagram of cable attenuation measuring set

$$Z_0 = b\sqrt{\epsilon}\log\frac{D}{d}\text{ ohms}$$

where ϵ is the dielectric constant of the insulating material, D is the inside diameter of the outer conductor, d is the diameter of the inner conductor, and b is a numerical coefficient. If the dielectric constant of the insulating material (polyethylene) does not vary, control of characteristic impedance reduces to control of capacitance. This follows from the fact that the capacitance C is related to the D/d ratio as follows

$$\frac{D}{d} = \text{antilog}\frac{k\epsilon}{C}$$

where k is a numerical coefficient.

Precision control of capacitance during the insulating process is achieved by a double-loop linear servo system, as shown in the simplified block diagram, Fig. 7. The two loops consist respectively of one capable of introducing relatively fast capacitance corrections of only modest accuracy, and of one capable of highly precise capacitance control on a relatively long time basis. The servo system controls the capstan payout speed of the central conductor feeding into the extruder applying the core insulation, as shown in the block diagram. Since the extruder delivers insulating material at a constant rate, an increase in central conductor speed results in a thinner-than-normal wall of insulation and thus causes an increase in capacitance.

The sensing element for the control loop consists of a capacitance monitor. This is a device capable of measuring the unit length coaxial capacitance of the cable core continuously as it moves through the water in the trough. Since the capacitance of a polyethylene-insulated core is temperature-sensitive, the monitoring electrode must be located at a point in the cooling trough where the temperature of the core is stable and known to a degree commensurate with the over-all accuracy objectives. The distance from the extruder to the electrode corresponds to about 10 minutes of cooling time; hence, a servo system based on this loop would be necessarily slow, because of the 10-minute delay in detecting a drift in capacitance.

Analysis shows that fast capacitance information of only moderate accuracy may be used in combination with the slow loop to speed up the response of the over-all system to a satisfactory degree, without sacrifice of precision of the slow loop. The sensing element used for the fast loop consisted of a light-ray diameter gauge, which measures the diameter (changes in diameter are the approximate inverse of the capacitance) of the hot core close to the extruder. The data for slow and for fast are combined to control the extruder, as shown in the block diagram.

The servo constants were chosen to minimize the deviations in unit length capacitance occurring in core lengths corresponding to less than one-fourth wave length of the top operating frequency. In other words, the objective for choice of servo loop constants was to assure equality in the capacitance of all one-fourth wave sections of core. Echo measurements indicated that a highly satisfactory degree of control was achieved. Over-all servo system performance was such that the standard deviation of the capacitance of the core lengths manufactured for the two crossings was ±0.1%. The capacitance monitor electrode and the servo console are illustrated in Fig. 8.

Adjustment of Concentricity

Means for setup and adjustment of the extrusion process to achieve relatively accurate centering of the conductor in its sheath of insulation was provided by a device called a concentricity gauge. This device operates on the principle that two small plane electrodes on opposite sides of the core will have different direct capacitances to the central conductor, when the conductor is not properly centered.

A simplified block diagram of the concentricity gauge is shown in Fig. 9. Data obtained with two sets of electrodes displaced 90 degrees were recorded on a strip chart recorder, with the output of the two sets of electrodes being displayed alternately. A satisfactory degree of centering was moderately easy to maintain.

Electrical Measurements

To assist in achieving the goal of matching the cable and the repeater characteristics with a minimum of deviation, electrical measurements were made throughout the process and close tolerances were placed on the electrical parameters in each stage of production. Measurements on the repeater section lengths of cable were used as a final check to determine the extent to which all of the controls had been successful. The primary standards used were calibrated by the Bureau of Standards in the United States or the National Physical Laboratories in England. These precision standards were used to calibrate the bridges frequently.

The d-c resistance of the central conductor was measured under constant

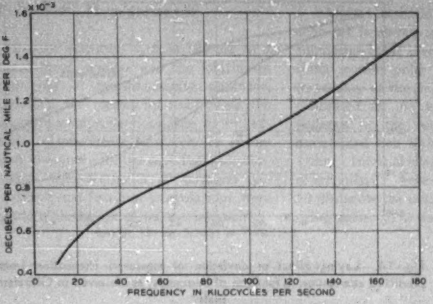

Fig. 11. Change in cable attenuation due to temperature as function of frequency

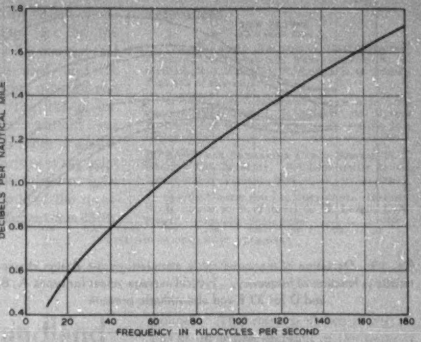

Fig. 12. Design characteristic of cable attenuation as function of frequency for 37 F and atmospheric pressure

temperature conditions with a precision type of Wheatstone bridge. The permissible range of resistance was 2.514 and 2.573 ohms per nautical mile at 75 F (degrees Fahrenheit). In practice, the spread of resistance values was well within these limits.

The 20-cycle core capacitance was also measured under constant-temperature conditions. For this measurement, the two ends of the central conductor were connected together and the measurements made between the central conductor and ground, which was provided by the water. A capacitance-conductance bridge was used for this purpose. The capacitance limits set initially were from 0.1726 to 0.1740 microfarad per mile at 75 F. Analysis of the core measurements shows that at each factory the range of capacitance was held more closely than indicated, which illustrates the benefits of servo control to the insulating process.

The d-c insulation resistance of the core was also measured by applying 500 volts for one minute. A minimum insulation resistance requirement of 100,000 megohm-miles at 75 F was established, but any lengths that had less than 500,000 megohm-miles were scrutinized for possible sources of trouble and were subject to rejection. As a general rule, insulation resistances considerably in excess of 500,000 megohm-miles were obtained.

The core was tested also at a voltage of 90,000 volts direct current for a period of one minute. This test was designed to catch any gross faults in the core caused by foreign particles which escaped detection by the other mechanical and electrical tests made on the core.

As discussed in the section on jointing, the core lengths were assembled and joined together to form a repeater section of cable. In general, an effort was made to produce the core for a repeater section of cable on a particular strander, extruder, and armoring line, and to join the lengths together in the order of manufacture. Practical difficulties such as the fact that the outputs of two stranders were required to supply one extruder made it impossible to achieve this objective in all cases.

Capacitance deviations from the desired nominal resulted from a variety of causes, such as inaccurate control of the temperature of the water in the core-cooling troughs and improper adjustment of the control apparatus. To minimize the reflection which would result from joining together two lengths of core of widely different capacitances, cores were not joined together if their measured a-c capacitances differed by more than 0.3%. When such capacitance differences did exist, the core length involved was removed from its normal sequence and placed in a position near the middle of the repeater section.

Because the taping and armoring processes were combined in one production line in the American factory, no other electrical measurements could be made on the components of the cable until it was completely armored. In the British factory, tests for information purposes only were made on the cable in the coaxial stage. These tests included measurements of attenuation, internal impedance irregularities, and terminal impedances. They served as a means of evaluating the changes in the electrical performance during armoring.

The insulation resistance requirement after armoring and storage under water for at least 24 hours was 100,000 megohm-miles. In addition, the cable had to withstand 50,000 volts for a period of one minute without failure.

Attenuation Measurements

As an aid in achieving the desired uniformity of product, new measuring equipment of improved accuracy was provided. A block schematic of this equipment is shown in Fig. 10. The requirements for this equipment were that it should be capable of measuring a 37- to 44-mile section of cable with an absolute accuracy of 0.04 db and a precision of 0.01 db in the frequency range from 1 to 250 kc.

The attenuation of the cable was measured at 10-kc intervals from 10 kc to 210 kc and measured values were corrected to 37 F, using the changes in attenuation owing to temperature, shown in Fig. 11. By comparing the corrected values with the design characteristic shown in Fig. 12, the deviations were determined. Both the attenuation characteristic and the changes in attenuation owing to temperature were derived from factory measurements of attenuation made on the Florida–Puerto Rico cable.

By comparing the running average and spread of these deviations with the design requirements, it was possible to assess the performance of the cable and, if required, to make any necessary adjustments in parameters for subsequent sections. In addition, these deviations were used to determine the length adjustment required for each repeater section to keep the sum of the deviations at each frequency in any one ocean block

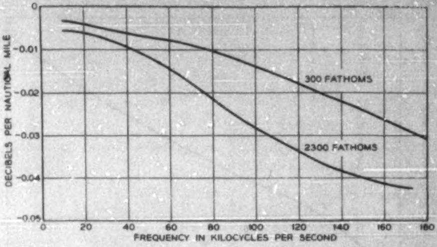

Fig. 14. Laying effect or deviation of measured attenuation from predicted attenuation as function of frequency, as observed in Gibraltar trials

to a minimum. Typical average attenuation deviation characteristics are shown in Fig. 13.

Temperature and Pressure Coefficients

Measurements of primary constants were made on 20-foot lengths of cable and core placed in a temperature-controlled and pressure-controlled tank. These measurements were used to compute the temperature coefficients of attenuation in order to check the values derived from measurements made on the Florida–Puerto Rico cable section. Additional attenuation measurements were made on several repeater section lengths of cable over a range of temperature from approximately 40 to 70 F, to establish further the magnitude of the changes in attenuation with temperature. The measurements indicated that the derived temperature coefficients were accurate to within ±10%.

Measurements also were made to determine the effect of pressure on the primary constants of the cable. These measurements indicated that capacitance was the only parameter affected by pressure. The capacitance increased linearly 0.1% for each 500 pounds per square inch of applied pressure. Since the attenuation α is inversely proportional to the impedance, it is evident that if C is the only parameter affected by pressure, α will also be affected by pressure to an amount equal to approximately one half the pressure effect on C. The pressure coefficient as α was therefore established as 0.05% per 500 pounds per square inch of pressure.

Laying Effect

Analysis of the Florida–Puerto Rico cable data indicated that the measured ocean bottom attenuation was less than the attenuation predicted from factory measurements. The differences were large enough to warrant study, and indicated that the measurements were in doubt, or that sea bottom conditions were not known accurately, or that some unexplained phenomenon was taking place.

In March 1955, approximately 22 mile of cable of the transatlantic design were laid in 300 fathoms of water off the coast of Spain in the Bay of Cadiz, and another equivalent length was laid in 2,300 fathoms off Casablanca. Precise measurements of attenuation were made in both cases, and it was established that a difference did, in fact, exist between measured values of attenuation at the ocean bottom and values predicted from factory measurements. It was further established that the difference in 2,300 fathoms was about twice that in 300 fathoms. The measured differences are shown in Fig. 14.

It was established during these trials that the difference increased slightly with time. Measurements made on the cable in 300 fathoms immediately, 18 hours, 48 hours, and 86 hours after laying indicated that measurable changes in attenuation were taking place. However, the change between 48 and 86 hours was so small, it was concluded that only very small changes would occur in a moderate interval of time. The tests also indicated that the attenuation of the two lengths of cable decreased somewhat during loading of the cable ship.

The total difference between the attenuation at the ocean bottom and the values predicted from factory measurements, taking the temperature and pressure coefficients into account, was designated "laying effect." Various theories, such as the consolidation of the central conductor, consolidation of return structure, and changes in the dielectric material, have been advanced to explain these differences. Each of these has been under study, but at the time of writing, no conclusive explanation has been established.

The shape of the "laying effect" versus frequency characteristic was such that the adjustment of repeater section lengths in conjunction with several fixed equalizers, which had approximately a 4-db loss at 160 kc and 0.6 db loss at 100 kc, would provide a good system characteristic. The matter of equalization is covered in greater detail in the article[4] on the over-all system. The magnitude of the laying effect observed during the laying of the two transatlantic cables substantiated the trial results.

BALANCING NETWORK
HYBRID COIL
PULSE GENERATOR
REPEATER SECTION OF CABLE UNDER TEST

Fig. 15. Simplified block diagram of pulse echo set for measurement of terminal impedance and internal impedance irregularities

Pulse Echo Measurements

Process controls, such as the use of a capacitance monitor and the jointing of the core in manufacturing sequence, provided the means for controlling the magnitude of reflections due to impedance mismatches. However, to ensure that the final product met these requirements, measurements of terminal impedance and internal irregularities were made with the use of pulse equipment.

A block schematic of the circuit of the echo set is shown in Fig. 15. For the submarine cable tests, a 1.5-microsecond raised cosine pulse was used, and the impedance of the balancing network was calibrated at 165 kc. The 165-kc impedance of the repeater sections was maintained well within a range of 54.8± 1 ohm. Internal irregularities at the point of irregularity were maintained at least 50 db below the magnitude of the measuring pulse. The requirement was 45 db.

System Design for the Newfoundland–Nova Scotia Link

R. J. HALSEY J. F. BAMPTON

Synopsis: The design and engineering of the section of the transatlantic cable system between Newfoundland and Nova Scotia was the responsibility of the British Post Office. Since the transmission objectives for this link were agreed upon in relation to the over-all objectives, this paper was written to show how these were translated into system and equipment design, and to demonstrate how the objectives were realized.

UNDER the terms of the agreement,[1] it was the responsibility of the British Post Office to design and engineer the section of the transatlantic cable system between Newfoundland and Nova Scotia. Like other parts of the system, all specifications were to be agreed upon between the Post Office and AT&T (American Telephone and Telegraph Company), but as both the British and the American types of submerged repeater had been carefully studied and generally approved by the other party prior to the agreement, the basic pattern of the system was clear from the beginning.

The service and transmission objectives for the over-all connections of London to New York and London to Montreal were agreed[2] in early joint technical discussions in New York and Montreal, and the agreed total impairments were divided appropriately between the various sections. In this way, the transmission objectives for the Newfoundland–Nova Scotia link were established.

Route

The choice of Clarenville as the junction point of the two submarine sections of the transatlantic system was determined primarily in relation to the Atlantic crossing and the desire to follow a transatlantic route to the north of existing telegraph cables.[3] There were a number of possibilities for the route between Clarenville and the east coast of Cape Breton Island, the most easterly point which could be reached reliably by the radio-relay system through the Maritime Provinces of Canada. One possibility, which had been considered earlier, was to cross Newfoundland by a radio-relay system and to use a submarine-cable link across Cabot Strait only. The final decision to build a cable system between Clarenville and Sydney Mines raised a number of problems in respect of the route to be followed which were concerned primarily with potential hazards to the cable brought about by:

1. The existence of very extensive trawling grounds on the Newfoundland Banks.
2. The location of considerable numbers of telegraph cables in the vicinity.
3. Grounding icebergs.

The route finally selected after thorough on-the-spot investigations[3–5] is satisfactory with respect to all these hazards, since it involves no cable crossings and is inshore of the main fishing grounds. This route is shown in Fig. 1. The straight-line diagram of the route is shown in Fig. 2. The total cable length is 326 nautical miles, of which 54.8 nautical miles are between Clarenville and Terrenceville, Newfoundland, where the cable finally enters the sea. The maximum depth of the water involved is about 260 fathoms.

Cable

Choice of Design

Since 1930, when the Key West–Havana no. 4 cable was constructed,[6] it has been usual to extrude the insulation of coaxial submarine cables to a diameter of about 0.62 inch, and most of the cables in the waters around the British Isles are of this size. The experience of the British Post Office with submerged repeaters[7] in its home waters, dating from 1944 when the first repeater was laid between Anglesey and the Isle of Man,[8] has therefore been mainly with 0.62 inch cables, first with paragutta as a dielectric and later with polyethylene. Most of these cables were originally operated without repeaters, and the 60-circuit both-way repeaters which are now installed on the routes were designed to match their characteristics.

In planning a new system, the size of cable will be determined by one of the following considerations:

1. Minimum annual charges for the desired number of circuits.
2. Terminal voltage required to feed the requisite number of repeaters.
3. Maximum number of repeaters or minimum repeater spacing which is considered permissible.
4. Maximum or minimum size of cable which can be safely handled by the laying gear in the cable ship.

When the 36-circuit system between Aberdeen, Scotland, and Bergen, Norway, was planned in 1952, the route length of 300 nautical miles greatly exceeded

that of any other submarine telephone system, and it was decided to use a core diameter of 0.935 inch, first, to keep the number of repeaters as low as seven, and second, because the system was intended as a prototype of a possible Atlantic cable. The cable dielectric is polyethylene grade *2* with 5% (per cent) of polyisobutylene.

For the Clarenville–Sydney Mines link it proved possible to design for minimum annual charges. With increasing experience and confidence in submerged repeaters, it was no longer considered necesssary to restrict the number of repeaters as for Aberdeen to Bergen, and the terminal-voltage requirements were reasonable. At the current prices of cable and repeaters in Great Britain, the optimum core diameter for 60 both-way circuits is about 0.55 inch, but the increased charge incurred by using 0.62-inch cable is less than 5% (0.62-inch core is optimum for 120 both-way circuits). To facilitate the manufacture and the provision of spare cable, it was therefore logical to adopt the same design as that proposed for the Atlantic crossing. This is described in other papers.[3,9]

After investigating various possible types of cable for the overland section in Newfoundland, it was decided to use a design essentially the same as the main cable, but with additional screening against external interference.[4] For the outer conductor and its copper-binding tape, the construction is identical with that of the main cable except that the compounded-cotton tape is overlapped. This construction is shown in Fig. 3. Outside this are five layers of soft-iron tapes each 0.006 inch thick, the innermost being longitudinal and the others having alternate right- and left-hand lays at 45 degrees to the axis of the cable. After another layer of compounded-cotton tape, there is extruded a polyethylene sheath 0.080 inch thick, and the whole is jute-served and wire-armored. As a check on the efficiency of the screening, the maximum sheath-transfer impedance at 20 to 100 kc was specified as 0.005 ohm per 1,000 yards.

It was thus possible to treat the entire link from Clarenville to Sydney Mines as a uniform whole, using the same type of repeater on the land as in the sea. A small hut at Terrenceville contains passive networks only.

Attenuation Characteristics

When the system was designed, precision measurements of cable attenuation were not available. The design of the Oban-Clarenville link was based on laboratory measurements on earlier 0.62-inch cable of a similar type, but the available data applied only to frequencies up to about 180 kc, whereas the Clarenville–Sydney Mines link was to operate at frequencies up to 552 kc. Extensive extrapolation was therefore involved. As soon as the first production lengths of cable became available in February 1955, laying trials were conducted off Gibraltar. It was found that there were serious changes of attenuation on laying, over and above those directly attributable to temperature and pressure effects, and that the assumed characteristics were inaccurate. Although the attenuation in the factory tanks had been in reasonable agreement with that of the earlier cable, there were changes on transfer to the ship's tanks and again on laying, amounting in all to a reduction of about 1.5% at 180 kc. This would have been comparatively unimportant

had the discrepancy been of "cable shape," i.e., the same fraction of the cable attenuation at all frequencies and therefore exactly compensated by a length adjustment of the repeater sections. As this was not so, and as the cable-equalizing networks in the repeaters were settled by this time, it was clear that precise information must be obtained so that suitable additional equalizers could be provided for insertion in the cable on laying. There are a number of factors which may lead to small changes of attenuation on laying, but most of these tend to increase the losses. The primary reason for the observed changes appears to be contact variations between the various elements of the inner and outer conductors, i.e., the wire and three helical tapes forming the center conductor and the six helical tapes forming the return conductor. These contact resistances tend to change with handling and, as a result of a slight degree of "bird caging" when coiled, it seems that the attenuation decreases as the coiling radius increases, and vice versa. Also, the effect of sea pressure is to consolidate the conductors and thereby further reduce the attenuation. This effect appears to continue on a diminishing basis for a long time after laying.

To obtain reliable data for the Clarenville–Sydney Mines link, 10 nautical miles of cable with *A*-type armor were laid off the Isle of Skye at about the mean depth of the system, 120 fathoms. The attenuations, coiled and laid, are shown in Fig. 4, with due allowance made for temperature and pressure. The ordinates, attenuation versus frequency, are such that the value should be approximately constant at high frequencies.

In making a final determination of the cutting lengths for the repeater sections, it was assumed that the factory measurements of attenuation would be reduced by 1.42% at 552 kc on laying, that the temperature coefficient of attenuation would be +0.16% per degree centigrade, and that the true pressure coefficient of attenuation was negligible at the depths involved.

Description of System

Circuit Provision and Frequency Allocation

It was originally thought that a design similar to that of the Aberdeen-Bergen system would be suitable for the Clarenville–Sydney Mines route in that it would provide 36 more circuits than the long section across the Atlantic. This potential excess capacity, which was required for circuits between Newfoundland and the Canadian mainland, disappeared when it was found that 36 circuits could, in fact, be provided over the longer link. The Aberdeen-Bergen design was therefore modified to provide a complete supergroup of 60 circuits, the same capacity as the earlier British projects.[7] The system thus requires broad-band transmission of 240 kc in each direction.

In the earlier British projects, the transmitted frequency bands were 24 to 264 and 312 to 552 kc, but for the present purpose the lower band is dropped by 4 kc to 20 to 260 kc, so that the lowest frequency is the same as on the Atlantic cables. This enables common frequency-generating equipment to be used at Clarenville for the two links and minimizes crosstalk problems. The main transmission bands and the allocation of the five 12-circuit groups are shown in Fig. 5, together with the ancillary channels. The facilities provided are discussed later.

Submerged Repeaters

The submerged repeaters which were used are fully described elsewhere,[10] and it will suffice to note here that they are rigid units, approximately cylindrical in shape, 9 feet long, and have a $10\frac{1}{2}$-inch maximum diameter. They are capable of withstanding the full laying pressure in deep water, although this is of little importance in the present application.

They are arranged for both-way

transmission through a common amplifier which has two forward paths in parallel, with a single feedback path. The two halves of the amplifier are so arranged that practically any component can fail in one without affecting the other.

Power-Feeding Arrangements

The submerged repeaters are energized by constant-current d-c supplies between the center conductor and ground. The power units at the two ends are in series aiding, and the repeater power circuits are in series with the center conductor, i.e., without ground connections, as in Fig. 6. This is the only arrangement by which it is possible to control the supply accurately at every repeater, the insulation resistance of cable and repeaters being sufficiently great that the current in the center conductor is virtually the same at all points. The constant-current feature of the supply ensures that repeaters cannot be overrun in the event of a ground fault on the system.

With this arrangement the link requires a total supply voltage of about 2,300 volts. The power-feeding equipment[12] at each terminal station is designed to feed a constant current of 316 milliamperes at this voltage, and it is permissible to energize the system from one end only, if necessary. The repeater capacitors which are the limiting factors in respect to line voltage are rated very conservatively at 2,500 volts, so that a single-ended supply of 2,300 volts, with the possibility of superimposed ground-potential differences, is near the desirable maximum. The two terminal power units are therefore designed to operate in series and to share the voltage.

With access to the cable provided at Terrenceville, it is possible to operate the power system on the following bases:

1. No ground at Terrenceville, power from both ends on a master-and-slave basis to ensure that the constant-current units do not build up an excessive voltage. This is the normal arrangement.
2. No ground at Terrenceville, power from one end only.
3. Ground at Terrenceville, with the Clarenville and Sydney Mines power units energizing the land and sea cables respectively. This arrangement has been particularly useful during the installation period.

The presence of high voltages on the cable constitutes a potential danger to personnel, therefore special precautions are taken in the design of the equipment in which the cable terminates and in which high voltages exist or may exist.

The ground connections for the power circuits at the two ends are via special ground cables, and ground plates are located about half a mile from the main cable. Metering arrangements are provided to check that the current does in fact take this path. These measures ensure that the current returning via the cable armor is never sufficient to cause serious corrosion.

Arrangement of Terminal Equipment

Fig. 7 shows the arrangement of the terminal equipment. In accordance with an early agreement precisely defining the various sections of the project, the link is considered to terminate at the group distribution frames at Clarenville and Sydney Mines, i.e., at the 60–108-kc interconnection points.

In addition to the cable-terminating and power-feeding equipments, *A* and *B*, the following are provided at the terminals:

1. Submarine-cable terminal equipment, *C*, consisting of repeaters to amplify the signals transmitted to and received from the cable, and equalizers and frequency-translating equipment to convert the line frequencies to basic supergroup frequencies, 312 to 552 kc.
2. Group-translating (group-bank) equipment, *D*, to convert the basic supergroup to five separate basic groups, 60 to 108 kc, and vice versa.
3. Equipment for the location of cable and repeater faults, *E* and *F*.
4. Speaker and printer circuit equipments, *G* and *H*, to provide two reduced-bandwidth telephone circuits, two telegraph circuits, and one alarm circuit for maintenance purposes. It is clear that such circuits should be substantially independent of the main transmission equipment.

Two principles were agreed upon very early in the planning; first, that the engineering of the various links should be integrated as far as possible, and second, that the items of equipment at each station should be provided by the party best in the position to do so. The result was that:

1. Items of standard equipment were provided by AT&T at Clarenville and Sydney Mines, and by the Post Office at Oban, thus simplifying maintenance and repair problems.
2. Basic power plant and the carrier supplies for supergroup and group translation were provided by AT&T for both terminal equipments at Clarenville.
3. Terminal equipment, special to the Clarenville–Sydney Mines link, was provided by the Post Office.

In view of the importance of the link, the power-feeding and transmission equipment are completely duplicated.

The submarine-cable terminal equipment is arranged to transmit the basic supergroup, directly over the cable in the east-to-west direction. In the west-to-east direction the supergroup is translated to the range 20 to 260 kc, using a 572-kc carrier.

Design of Transmission System

Performance Requirements

The agreed transmission objects for the Clarenville–Sydney Mines link were as follows:

Variation of Transmission Loss. The variation in the transmission loss of each group should have a standard deviation not greater than 0.5 db (decibel). This implies that the variation from nominal should not exceed 1.3 db for more than one per cent of the time.

Attenuation/Frequency Characteristics. Only the over-all characteristics of the individual circuits were precisely specified, the limits being the CCIF (International Consultative Committee on Telephony) limits for a 2,500-km (kilometer) circuit and the target one half of this. With this objective in view, the group characteristics in each link must clearly be as uniform as is practicable.

Circuit Noise. The total noise contributed by the link to each channel in the busy hour, i.e., including intermodulation noise, should have an rms value not exceeding +28 dba (decibels adjusted),* which corresponds to −56 dbm (decibels referred to one milliwatt), at a point of zero relative level.

Crosstalk. The minimum equal-level crosstalk attenuation should be 61 db for all sources of potentially intelligible crosstalk; this was accepted as a target for both near- and distant-end crosstalk. Although go-to-return crosstalk is not important for telephony (it appears as sidetone) and a limit of 40 db is satisfactory even for voice-frequency telegraphy, it assumes great importance for both-way music transmission. Also, it was desired to be nonrestrictive of future usage.

Assessment of Requirements

The design of the high-frequency path to meet the agreed requirements involves consideration of the following:

1. Noise, including fluctuation (resistance and tube) noise and intermodulation.
2. Wide-band frequency characteristics, including the effects of the directional filters at the terminal and in the repeaters.
3. Variations of 1 and 2 with respect to temperature and aging.

The noise requirement is by far the most important factor in the design of the line system.

The choice of route and cable having been made, the total loss was known, and it was necessary to determine the minimum number of repeaters to compensate for this loss and to meet the noise requirement with adequate margin for inaccurate estimates of capable attenuation after laying, temperature variations, aging, and repairs. An attempt to achieve the necessary gain with too few

* This refers to the reading on a Bell System *2B* noise meter (F1A weighting network). The noise level, dba, is relative to a 1.0-kc tone at −85 dbm. In Europe, noise is measured on a CCIF psophometer (1951 weighting network), which is calibrated in millivolts across 600 ohms. This is commonly converted to picowatts (pw). The white noise equivalence of the two instruments is given by dba = 10 $\log_{10}$ pw − 6 = dbm + 84. The agreed limit of +28 dba is therefore equivalent to 2,513 pw (1.23 millivolts or −56 dbm). The corresponding CCIF requirement at 4.0 pw per km would be 2,400 pw, this value not to be exceeded for more than one per cent of the time.

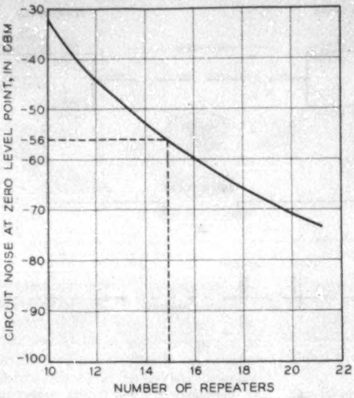

Fig. 8. Variation of circuit noise with number of repeaters

repeaters would result in excessive noise.

Design of the amplifiers in the British repeaters is such that, with both forward paths in operation, the overload point is about +24 dbm, and with a loading of 60 channels in each direction, this permits planning levels of about −4 dbm at the amplifier output after allowing reasonable margins for errors and variations.[10] Previous experience shows that, at such output levels, intermodulation noise can be neglected and the full noise allowance allotted to fluctuation noise. The effect of tube noise is to increase the weighted value of resistance noise by about 1 db to −137.5 dbm, or −53.5 dba, at the input to the amplifier in each repeater.

At the highest transmitted frequency the equalizers, power filters, and directional equipment introduce losses of about 1 db and 4 db at the input and output of the amplifier respectively; these losses must, effectively, be added to the loss in the cable.

The two other items of information which are necessary before the repeater system can be planned are the permissible transmitting and receiving levels at the shore stations. The transmitting equipment, provided at Clarenville can be operated at channel levels up to +20 dbm, and it is logical to allow the same receiving level at the shore end as at intermediate repeaters.

On this basis it is possible to construct a curve, Fig. 8, relating the total circuit noise to the number of intermediate repeaters, and it is seen that the minimum number is 15, each of which must have an over-all gain of 59 db (amplifier gain, 64 db) at 552 kc. The actual provision is for 16 repeaters, each having a gain of 60 db at 552 kc, the additional gain being absorbed in fixed and adjustable networks at points along the route, as indicated in the following section.

Level Diagram

The actual level diagram (planning levels are shown in Fig. 9) differs somewhat from that which can be deduced directly from the preceding section because of the following considerations:

1. The location of the first repeater from Clarenville, i.e., on land, was dictated by topography and the desire to locate both it and the second repeater in ponds. Thus, the transmitting level at Clarenville is substantially lower than the permissible maximum.
2. There are equalizing networks at Terrenceville and facilities for their adjustment to compensate for temperature variations.
3. Because of the difference between the actual cable attenuation and that for which the repeaters were planned (see the section "Attenuation Characteristics"), it was necessary to include an equalizer unit in the sea, midway between Terrenceville and Sydney Mines. Loss equivalent to 9 nautical miles of cable was also introduced at this point to ensure that repeater no. 16 would be sufficiently far from the shore at Sydney Mines.
4. Cable simulators are included in the cable-terminating equipment at Sydney Mines to build out this section to a standard

repeater section. The actual cable length was, of course, unknown until the cable was complete.

Taking into account the existence of the intermediate networks, the repeater spacing is such that, when both land- and submarine-cable sections are at mean temperature, the compensation is as accurate as possible. In general, the highest frequency is of greatest importance in this respect. Since the low-frequency channels experience less attenuation than the high-frequency channels, it is permissible to transmit them at a somewhat lower level, thereby increasing the load capacity of the amplifiers, which is available to the high-frequency channels.

TEMPERATURE EFFECTS AND THEIR COMPENSATION

The effect of temperature changes is likely to be somewhat complex. The land-and-sea cable sections are expected to behave in different ways in this respect, but data on the manner of variation are not very precise. The submarine cable crosses Cabot Strait, where melting icebergs, drifting down from Labrador as late as June, can be expected to keep the sea-bottom temperature low until well into the summer. Temperatures just below 0 C (degrees centigrade) were, in fact, recorded when the cable was laid in May. On land, the cable is buried 3 feet deep in bog and rock, and traverses many ponds. Some data on temperatures during similar conditions in other parts of the world were available.

For planning purposes, it was clear that the assumptions made would have to be somewhat pessimistic, and the assumed ranges of temperature, with the corresponding changes of attenuation at 552 kc, were:

Sea section............2.3±3 C; ±4 db
Land section...........7.5±10 C; ±3 db

A possible method of circuit adjustment for temperature changes is to increase the gains equally at the sending and receiving terminals, as the temperature rises, and to reduce them equally as it falls. Under such conditions, the effect of temperature variations on resistance noise is not very important; the levels at repeaters near the center of the route remain substantially constant, and the increase in noise from the repeaters whose operating levels are reduced is partly compensated by the reduction in noise from those whose levels are increased. The effect of the level changes on repeater loading is, however, more important, as it is undesirable that any repeater in the link should overload. Additional measures which can be readily adopted to avoid serious changes in repeater levels are clearly desirable.

The estimated change of attenuation of the land sections is seen to be roughly equal to that of the submarine section, so that, from the point of view of temperature changes, Terrenceville is near the electrical center of the link. It was thus both desirable and convenient to provide adjustment at this point. Fig. 10 illustrates the advantage of seasonal changes in equalizer setting at Terrenceville, showing the way the output levels of repeaters are likely to vary along the route. The system of temperature compensation which was adopted therefore involves adjustable networks at both ends of the system and at Terrenceville. All the networks are cable simulators, thus, the process of temperature compensation consists, effectively, in adding cable when the temperature falls and removing it when the temperature rises.

At Terrenceville, the networks permit adjustments equivalent to ±1 nautical mile of cable (3 db at 552 kc), but at Clarenville and Sydney Mines adjustments equivalent to 0.5 db at 552 kc are provided. It should therefore always be possible to maintain the over-all loss of the system within ±0.25 db, and the level at any repeater should never change by more than ±2 db.

SYSTEM PILOTS

The use of pilot tones, applied at constant level at the input of a system with indicating or alarm meters at the receiving end, is standard on land systems on both sides of the Atlantic, although the philosophies underlying the methods of use differ. On the submarine cables round the British Isles, with or without submerged repeaters, pilot tones are used to indicate the attenuation of the transmission path. These pilots are normally located just outside the main transmission bands in each direction. In the Clarenville–Sydney Mines system, the frequency bands just outside the main transmission bands are occupied by telephone speaker and teleprinter circuits and by monitoring frequencies associated with the repeaters (see Fig. 5). This prevents the use of out-of-band pilots.

Fortunately, the standard Bell System group equipment is designed to apply 92-kc pilots to each group and to measure the corresponding received level. Although these are essentially group pilots, being applied and measured at points in the 60- to 108-kc band, it was decided that they could reasonably replace the out-of-band pilots. These pilots are blocked at each end of the system and therefore function as section pilots only.

Normal Post Office practice, both on land and submarine systems, is to use recording level meters to provide a continuous and permanent record of the pilot levels. In the present system such recording meters are used on the 92-kc pilots of two groups, in each direction of transmission.

In addition to the section pilots, the system carries the 84.080-kc end-to-end pilots in each of the three transatlantic groups.

Maintenance Facilities

SPEAKER AND PRINTER CIRCUITS

It was part of the planning of the transatlantic system that two low-grade telephone (speaker) and two telegraph (printer) circuits should be provided over the submarine cables, outside the

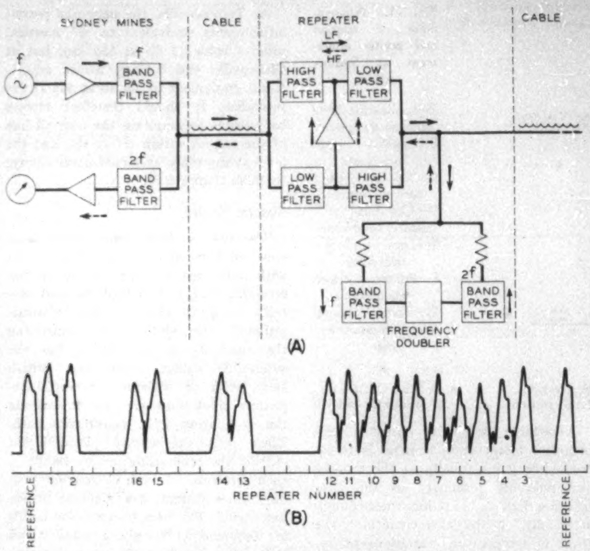

Fig. 12. Fault location, loop-gain method

A—Block schematic, frequency f is in the band 260 to 264 kc
B—Diagram of display

main transmission bands, and that the speaker circuits, in particular, should be reasonably independent of the main terminal equipment. One speaker circuit is needed for local communication between the terminals of each section, the other is needed to form part of an omnibus circuit which connects the principal stations on the route, including Montreal. The arrangement for teleprinter communication was that one channel should be an over-all all-station omnibus printer, while the other should be a direct London–New York printer.

Independent frequency-translating equipment is provided to connect the speaker and printer bands, each 4 kc, to the line. The carrier frequencies required for the speaker are provided by independent oven-controlled crystal oscillators, but, for the printer, the independent generation of high-stability 572-kc carriers was not considered to be justified, and the main station supplies are used.

Two half-bandwidth telephone circuits are provided in the 4-kc speaker bands by the use of standard AT&T band-splitting equipment (EB banks). Signalling and telephone equipment are provided to give the required omnibus facilities on one circuit and local-calling facilities on the other. The arrangement of the speaker and printer equipment at Sydney Mines is shown in Fig. 11.

In the telegraph band, a third channel transmits an alarm to the remote terminal when the 92-kc pilots, coming in from that terminal, fail simultaneously.

FAULT LOCATION

The speedy and accurate location of faults in repeatered cables is of very great importance, because of the number of circuits involved and the difficulty and cost of repairs. The standard d-c methods which have been applied in the past to long telegraph cables are, of course, available. The application of these methods is, however, recognized as being rather more in the nature of an art than a science and usually requires an intimate knowledge of the behavior and peculiarities of the particular cable concerned. While the problem appears at first to be simple, it is complicated by:

1. The presence of ground-potential differences along the cable, sometimes amounting to hundreds of volts. These vary with time.
2. Electrolytic electromotive force generated when the center conductor is exposed to sea water.
3. Absorption effects in the dielectric of the cable. When repeaters are added, the position is further complicated by items 4 and 5.
4. The lumped resistance of the repeaters, which is current dependent and exceeds the cable resistance.
5. The lumped capacitance of the repeaters with an absorption characteristic which differs from that of the cable.

It is a great advantage of both-way transmission over one cable that, by introducing some form of frequency changer at each repeater, signals outgoing in one direction can be looped back to the sending terminal. There have been a number of developments based on this principle and, in the Clarenville–Sydney Mines link, two methods are available for use. Of these, the so-called "loop-gain" method uses steady tones and depends on selective frequency measurements to discriminate between repeaters; the second is a pulse method in which repeaters are identified on the basis of loop transmission time.

The use of these methods during fault conditions depends on the possibility of keeping the repeaters energized. Work is in progress to develop methods of fault location which are of general application and do not depend on the activity of the repeaters, but these are outside the scope of this paper.

Loop-Gain Method

In the loop-gain method, the frequency changer in the repeater takes the form of a frequency doubler, and each repeater is identified uniquely by one of a group of frequencies spaced at 120 cycles and located immediately above the lower main transmission band in the frequency range of 260 to 264 kc. Since the frequency changing is in an upward sense, the measuring terminal is Sydney Mines, which transmits the lower band. On the Clarenville side of the directional filters, in each repeater is connected, via series resistors, a crystal filter accepting the test frequency appropriate to the repeater; see Fig. 12(A). This frequency is doubled, filtered, and returned to the repeater at the same point at which the original frequency is selected. From this point it passes via the high-pass directional filters through the amplifier and back to Sydney Mines, where the level is measured on a transmission-measuring set. Information obtained in this way on each repeater can be compared at any time with that obtained when the system was installed, and any

B—Clarenville to Sydney Mines

gain variations can be localized. The test equipment provided has the additional facility of an automatic sweep of the test frequency at 4 cycles and has a display of the returned-signal levels on a cathode-ray tube as shown in Fig. 12(B).

Although the transmitted signals lie outside the band of the west-east supergroup, the received signals, 520 to 528 kc, lie within the band of the east-west supergroup, and two channels must be removed from traffic to carry out the tests. These channels are in a "local" group.

Pulse Method

As applied to the present system, the pulse method uses the overload characteristic of the amplifier to effect the frequency change in the repeater. At Sydney Mines, a continuous train of single-frequency pulses is applied in the lower transmission band, so that either the second or third harmonic is returned in the upper band, as shown in Fig. 13. At Clarenville, 2-frequency pulses are applied in the upper band, so that either a second- or third-order difference product is returned in the lower band. The pulse length is 0.15 millisecond, and the frequencies used are given in Table I. At Sydney Mines, the signals can be sent and received either on the line itself or via the group equipment. In the latter case, only one group need be taken out of service. At Clarenville line, only measurements are provided for.

The primary display is on a cathode-ray tube with a circular time base, and any one returned pulse can be accurately compared with the reference pulse on a second tube with a linear time base. The pulse selected for such measurement is automatically blacked out on the primary display.

Usefulness of Loop-Gain and Pulse Methods

Both methods require that all the repeaters between the testing terminal and the fault can be energized. If the fault is in the cable, there is a very high probability that the center conductor will be exposed to the sea, in which case the power circuit can be maintained at least on one side of the fault, although it may be somewhat noisy. Because the system is short, it is permissible to energize the link fully from one end only. The condition can never arise, as it can in the Oban-Clarenville link, that the line current is limited by the maximum permissible terminal voltage.

The loop-gain test is concerned with the amplifiers in their linear regime and gives no indication of the overload point. For this, the pulse test must be used. On the other hand, the pulse test does not permit accurate measurement of levels, since the pulse level which reaches a particular repeater may be restricted by the overload of an earlier repeater in the chain. The pulse test is particularly useful in providing a check to see that both sides of each amplifier are in operation and to locate a fault of this type.

Each method, for its operation, depends on nonlinearity at a point within each repeater and can only identify a fault as lying between two such consecutive points in the link. It is therefore desirable that these points should be as close as possible to the terminals of the repeater to ensure that the faulty unit can be identified. In this respect, the loop-gain test has the advantage over the pulse test.

Execution of Work

Problems caused by the remoteness of the site were overcome without undue difficulty with the co-operation of the other parties concerned with the project, but this paper would be incomplete without a brief reference to the cable- and repeater-laying operations in Newfoundland and at sea.

The terrain and conditions in Newfoundland were quite unlike those with which the British Post Office normally has to contend, since they involved trenching and cabling through bog, rock, and ponds in country of which no detailed survey or maps were available. Maps were constructed from aerial survey, and alternative routes were explored on foot before a final choice was made. As much use as possible was made of water sections in the sea, river estuary, and ponds; some 22 miles were accounted for in this way, leaving about 41 miles to be trenched by machine or blasted. A contractor was engaged for this purpose and to lay the cable in the trench, but all jointing was done by the Post Office. The standards of conductor and core jointing were the same as those in the cable factories and on ship, with portable injection-moulding machines and X-ray equipment specially designed for handling over the bog. A single-pair cable was also laid in the main cable trench to provide speaker facilities between Clarenville and Terrenceville, which has no public telephone, with intermediate positions for use of the lineman. As a measure of protection against lightning strikes, two bare copper wires were buried about 12 inches apart and 6 inches above

Table I

Station	Send to Line		Product	Receive, Kc
	f_1, Kc	f_2, Kc		
Sydney Mines	216		$2f_1$	432
	144		$3f_1$	432
Clarenville	530	380	f_1-f_2	150
	530	340	$2f_2-f_1$	150

the cable. Both the constructional work in Newfoundland[4] and the laying operation at sea[5] have been described elsewhere.

Test Results

In the interval between the completion of the link in May 1956 and its incorporation in the transatlantic system, tests were carried out to establish its performance and day-to-day variations. An assessment of the annual variations has, of course, been impossible at present.

VARIATION OF TRANSMISSION LOSS

Close observation of the transmission loss of the 92-kc pilots on groups 1 and 5 leads to these tentative conclusions:

1. Over periods of one hour, the variations are not measurable, i.e., less than ±0.05 db.
2. Over periods of 24 hours, there are no systematic changes; apparently random changes of about 0.1 db are probably attributable to the measuring equipment.
3. Over a period of 8 weeks, July and August 1956, there was a systematic increase in loss of about 0.3 db. By means of the loop-gain equipment, it has been possible to deduce that most of this change has occurred in the land section.

The results indicate that the submarine-cable link has better day-to-day stability than the best testing equipment which it has been possible to provide. Many more data will clearly be necessary before the annual variations can be established definitely, but the present indications are that these variations will be less than those assumed in the design of the link.

ATTENUATION/FREQUENCY CHARACTERISTICS

The frequency characteristics of the supergroup in the two directions of transmission are shown in Fig. 14. It will be seen that in no transatlantic groups does the deviation from mean exceed ±0.35 db.

CIRCUIT NOISE AND CROSSTALK

Table II shows the noise level on channels 1 and 12 of each of the five groups measured without traffic on the system.

To assess the magnitude of intermodulation noise, all channels in one direction were loaded simultaneously with white noise, and measurements were taken on each channel in the opposite direction. From the talker volume data assumed in the design of the system, the expected mean talker power is −11.1 dbm at a point of zero relative level, with an activity of 25%. For an equivalent system loading, therefore, the level of white noise applied to each channel under these test conditions should be −14.1 dbm. Since this loading gave no sensible increase in the circuit noise, the test levels were raised until a reasonable increase in the noise level was obtained. In order to raise the channel noise to the specified maximum of 28 dba, it was necessary to raise the channel levels to about −1 dbm and −4 dbm in the lower and upper bands, respectively. These levels, some 13 db and 10 db above the assumed maximum loading of the system, give noise levels at least 26 db and 20 db above normal, and it is seen that adequate margins exist for variations and deterioration of the link.

Closely allied to the problem of intermodulation is the overload characteristic of the system. Table III shows the measured overload point of the link, expressed as an equivalent level at the output of the amplifier in the repeater nearest to the transmitting terminal. It also shows the margin between the channel level at that point and the overload point of the system. According to Holbrook and Dixon,[13] the minimum requirement in this respect is 18 db.

These results justify the assumption made in the design of the link, that intermodulation noise is negligible.

The crosstalk requirements are met in all respects.

Conclusions

The submarine-cable link between Clarenville, Newfoundland, and Sydney Mines, Nova Scotia, was completed in May 1956 and provides five carrier telephone groups, each capable of carrying twelve high-grade telephone circuits or their equivalent. The transmission objectives have been met in every respect.

Three 12-circuit groups are connected to the three groups across the Atlantic, between Scotland and Newfoundland. The other two groups are available to provide 24 circuits between Newfoundland and the mainland of Canada.

Acknowledgments

It has been the authors' privilege to present an integrated account of the work of many of their colleagues in the Post Office and in industry. The Post Office staff have been responsible for designs and inspection, and for testing at home and in the field, as well as the laying of the submarine-cable system by *HMTS Monarch*. In Great Britain, Submarine Cables, Ltd., and the Southern United Telephone Company, Ltd., provided the submarine and overland cables respectively, while Standard Telephones and Cables, Ltd., supplied and contributed much to the design of the submerged repeaters and terminal equipment. On site, the assistance rendered by the Ordnance Survey of Great Britain; the Canadian Comstock Company, Ltd., who laid the cable across Newfoundland; the Northern Electric Company, Ltd., who carried out the terminal equipment installations; and by the other partners in the project, the American Telephone and Telegraph Company, Inc.; the Canadian Overseas Telecommunication Corporation, and the Eastern Telephone and Telegraph Company has been invaluable. The permission of the Engineer-in-Chief of the Post Office to make use of the information contained in the paper is gratefully acknowledged.

Repeater Design for the Newfoundland–Nova Scotia Link

R. A. BROCKBANK D. C. WALKER V. G. WELSBY

Synopsis: The Newfoundland-Nova Scotia cable required the provision of 16 submerged repeaters each transmitting 60 circuits in the bands 20 to 260 kc from Newfoundland to Nova Scotia, and 312 to 552 kc in the opposite direction. This paper deals with the design and production of these repeaters. Each repeater has a gain of 60 db (decibels) at 552 kc, and the amplifier consists of two forward amplifying paths with a common feedback network. Reliability is of paramount importance, and production was carried out in an air-conditioned building with meticulous attention to cleanliness and to very rigid manufacturing and testing specifications. The electrical unit is contained in a rigid pressure housing 9 feet long and 10 inches in diameter with the sea cables connected to an armor clamp and a cable gland at each end. A submerged equalizer was provided near the middle of the sea crossing.

THE BRITISH POST OFFICE has engineered many shallow-water submerged-repeater systems,[1] and there has been a progressive improvement in design techniques and in the reliability of components, which has reflected a growing confidence in the ability to provide long-distance systems having an economic life. The 7-repeater scheme from Scotland to Norway laid in 1954 introduced for the first time repeaters which would withstand the deepest ocean pressure, together with an electrical circuit which embodied improved safety and fault-localizing devices. Also, since a repeater is only as reliable as its weakest component, much greater attention and control were directed at this stage to the design, manufacture, and inspection of all components, both electrical and mechanical. This repeater design was, in fact, envisaged as a prototype for a future transatlantic project.

In the finalized plans[2] for the Newfoundland-Nova Scotia cable it was required to carry 60 circuits, so that some redesign of the 36-circuit "prototype" repeater became essential. It was accepted, however, as a guiding principle throughout the redesign that there should be no departure from previous practice without serious consideration and adequate justification. It was obviously not an occasion to experiment with new ideas.

Experiences of the Post Office and Bell Telephone Laboratories were pooled for the project, and the technical resources of both organizations were freely available at all times for consultative purposes. Detailed manufacturing and testing specifications were exchanged and approved, and each party was free to inspect the other's production methods. This mutual interchange was undoubtedly highly beneficial, and in the British case it resulted in a still more rigorous control of manufacturing and inspection methods.

Planning

General

Preliminary design calculations indicated that it should be possible to increase the circuit-carrying capacity of the Anglo-Norwegian prototype repeater from 36 to 60 circuits, and tests on a model confirmed that, with band frequencies of 20 to 264 and 312 to 552 kc, a 60-db gain at 552 kc could be realized with satisfactory margins against noise, distortion, and overload. This gain fixed the repeater spacing at about 20 nautical miles, so that on the selected route two repeaters would be required on the land section between Clarenville and Terrenceville, and 14 in the Terrenceville-Sydney Mines sea section. It was noted that the land repeaters might have to work with an ambient temperature of 12 C (degrees centigrade) higher than in the sea repeaters.

Each repeater would need to be energized with a direct current of 316 ma (milliamperes) at 124 volts, so that the total route voltage would be about 2,300 volts. This voltage would be quite acceptable to the repeaters, but for normal operation it was proposed[2] to feed from both terminals simultaneously, thereby halving the maximum voltage to ground.[3]

The precise localization of any faulty or aging repeater would be of paramount importance. It was decided to retain the two supervisory methods which on the prototype had worked satisfactorily in this respect. These consisted of a pulse-distortion equipment requiring no additional components in the repeater, and a loop-gain monitoring set involving a special unit in the repeater and the allocation of a 4-kc band (260 to 264 kc) for its operation.

Manufacture and testing of the electrical units was again to be carried out by a contractor in a temperature- and humidity-controlled production building. To enable manufacture to start as early as possible, arrangements were made for the contractor to co-operate with the Post Office at an early design stage, so that engineering could follow fast on the heels of the design. The outer housing and method of brazing-in the bulkheads had all proved entirely satisfactory on the prototype, and therefore these operations could proceed as in previous production.

A Conference Paper presented at the Symposium on the Transatlantic Submarine Telephone Cable, during the AIEE Winter General Meeting, New York, N. Y., January 21–25, 1957.

R. A. Brockbank, D. C. Walker, and V. G. Welsby are with the British Post Office, London, England.

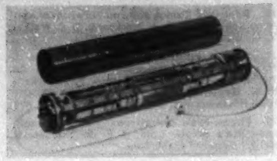

Fig. 1. Internal unit

The Post Office assumed responsibility for the production and testing of the glands, since no contractor had experience of this work.

Forward planning in early 1954 scheduled the first electrical unit to be completed in June 1955, with units following at 5-day intervals. This target was, in fact, delayed until August 1955, but all 16 working repeaters were fully tested and available before the commencement of the laying operation in May 1956.

Distortion Monitoring Equipment

The pulsed-carrier supervisory method, as used on previous systems,[1] is employed primarily for measuring the distortion on repeaters. Under normal operating conditions the distortion level may be only just noticeable above the noise but, should appreciable distortion occur, e.g., failure of one amplifying path in a repeater, it could be readily located, since the pulse amplitude from the faulty repeater would increase by about 12 db for second-harmonic distortion and about 18 db for third-order distortion.

Loop-Gain Monitoring Equipment

For the loop-gain monitoring equipment[1] the repeaters have to be designed to incorporate a second-harmonic generator operating at a frequency unique to each repeater at 120-cycle spacing in the 260- to 264-kc band. The second harmonics return to Sydney Mines in the 520- to 528-kc band, and these two channels must be taken out of service during the measurement.

Levels and Equalization

Controlling Factors

In practice, deviations from an ideal system, wherein all repeaters match the cable and operate at all times at the same levels, require the repeaters to be designed with specific margins against overload and intermodulation to meet an agreed maximum noise figure for the system under all working conditions.[2] Factors involved in assessing these margins and in planning the equalization and level diagram for the system are:

Temperature. The final, assumed sea-bottom temperature was 2.3 C, with a maximum annual variation of ±3 C. The maximum change in attenuation might therefore be ±4 db at 552 kc. The land section change would be ±3 db at 552 kc due to a possible ±10 C change on a mean of 7.5 C. The effect of these seasonal changes would be reduced by the provision of manually adjusted equalization at Clarenville, Terrenceville and Sydney Mines.

The repeaters show a small change in gain (less than 0.05 db) during the warming-up period after energization, but the effect of ambient-temperature change is negligible.

Repeater Spacing. The repeater-section cable lengths were to be cut in the cable factory in such a way that the expected attenuation at 552 kc, when laid at the presumed mean annual temperature of the location, should be 60.0 db. An anticipated decrease in attenuation of 1.42% (per cent) at 552 kc was assumed when laid. The assumed mean annual temperature of sections of the route varied between 1.7 and 4 C. Temperature corrections employed an attenuation coefficient at 552 kc of +0.16% per C. It was expected that the total error at 552 kc after laying seven repeaters would not exceed 1.5 db, and this could be largely corrected as explained in the following.

Cable Characteristics. The cable equalization built into the repeater was based on a cable attenuation characteristic which was later discovered to be appreciably different from the laid characteristic. Cutting the cable as described in the foregoing overcomes this difficulty at 552 kc, where the signal-to-noise ratio is at a minimum. The new shape of the characteristic, however, indicated that at about 100 kc the error would reach 7 db on the complete route. To reduce this deviation it was decided to introduce a submerged equalizer in the middle of the sea section to correct for half this error, and to insert, in each of the 4-wire paths of the transmit and receive equipments, equalization for one-quarter of this error. There is an appreciable signal-to-noise margin in hand at this frequency, so that the system would not be degraded below noise specification by these equalizer networks.

It was also decided that the splice at the equalizer which would connect the halves of the link together should not be completed until after the laying operation had commenced. An excess length of cable was provided on the equalizer tail, and this could be cut at a position indicated by measurements taken during the laying of the first half-section, so that the equalization at the 552-kc point could be largely corrected for laying and temperature-coefficient errors. In practice, it is not easy to separate these two factors.

Repeater Characteristic. The repeater was designed to equalize the original cable-attenuation characteristic to ±0.2 db, as this was possible with a reasonable number of components. This variation appeared as a roll in the gain/frequency characteristic, which was expected to be systematic and would therefore lead to a ±3-db roll in the over-all response. It was proposed that equalization for this should be provided at the receive terminal. Manufacturing tolerances were expected to be small and random.

Repeater Interaction. At the lower frequencies, where the loss of a repeater section is comparatively small, a roll in the over-all frequency response will arise, due to changes in the interaction loss between repeaters. The design aimed at providing a loop loss greater than 50 db, which would reduce rolls to less than ±0.03 db per repeater section, and therefore to about 0.5 db at 20 kc with systematic addition on the whole route.

Planning of Levels

From a critical examination of all these variables it was concluded that the repeater should be designed to have an overload margin of 4 db above the nominal mean annual temperature condition. It was also desirable that the system be able to operate within its noise allowance, if one path of a twin amplifier failed. Tests on a model amplifier gave overload values of +24 dbm (decibels referred to 1 milliwatt) and +19 dbm for 2- and 1-path operation respectively, so that with a single-tone overload requirement of 18 dbm[4] at a zero-level point, the maximum channel level at the amplifier output would be −3 dbr (decibels referred to reference noise) for a single amplifying path.

Thermal-noise considerations (i.e. resistance plus tube noise) fixed the minimum channel level at the repeater input at −69 dbr for the purpose of meeting the allowable system noise limit of +28 dba at a zero-level point. At 552 kc the amplifier gain is 65 db, so that the minimum level at the amplifier output is −4 dbr. A system slope of ±4 db due to temperature variations, corrected by similar networks at the transmit and receive terminal, would,

however, degrade the noise by 0.5 db. Intermodulation noise was estimated[8] on an average busy-hour basis, and it was concluded that the increase in noise at 552 kc from this source was negligible: less than 1 db, even with several repeaters in which the amplifier had failed on one path. At lower frequencies the contribution from intermodulation noise is greater, and at 20 kc it exceeds resistance noise. However, at 20 kc the total noise is some 8 db below the specification limit, and therefore again several amplifiers could fail on one path before the noise exceeded the specification limit. Actually it was discovered that the predominant source of third-order intermodulation on the repeater was in the nickel-iron/ceramic seals on high-voltage capacitors and followed a square law with input levels.

From a more detailed examination of the factors briefly mentioned in the foregoing, it was decided that the initial line-up should be based on a nominal flat −3.5-dbr point at the amplifier output and the final working levels decided upon as the results of tests on the completed link.

With equal loading on the grid of the output tube at all frequencies, the worst signal-to-noise ratio exists at 552 kc; some pre-emphasis on the transmit signal should therefore prove beneficial. In fact, after completing the tests on the link, it was decided to improve the margin on noise by raising the level at 552 kc by 2 db, thus giving a sloping level response at the amplifier output in the high-frequency band. To maintain the same total power loading, the low-frequency band levels were decreased by one db, still retaining a flat response.

LAYING

It was proposed to use laying methods with continuous testing similar to those employed successfully on the Anglo-Norwegian project. The complete link with a temporary splice at the equalizer would be assembled and tested on board *HMTS Monarch* and laying would proceed from Terrenceville to Sydney Mines in the high-frequency direction of transmission. A detailed description of the actual laying operation is given elsewhere.[9] After completion of tests on the submarine section, the land section to Clarenville would be connected with appropriate equalization at Terrenceville.

Design of Electrical Unit of Submerged Repeater

GENERAL

The electric equipment is contained in a hermetically sealed, brass cylinder (filled with dry nitrogen) $7^3/_4$ inches in diameter and 50 inches long, which is bolted at one end to one of the bulkheads of the housing. A flexible coaxial cable emerges through an O-ring seal at each end, and these are ultimately jointed to the cable glands. The various units forming the complete electrical unit are mounted within a framework of Perspex (polymethylmethacrylate) bars which forms the main insulation of the repeater, and these units may operate at 3-kv d-c to the grounded brass cylinder. Fig. 1 shows the construction.

A schematic of the electric circuit is given in Fig. 2. The direct current for energizing the repeater is separated from the carrier transmission signals by the *A*- and *B*-end power-separating filters, and passes through the amplifier tube heaters and a chain of resistors which develops the 90-volt high-voltage supply for the amplifier. The carrier-frequency signals pass through the same amplifier

via directional filters. Equalization is provided in the amplifier feedback circuit (about 20 db) and in the equalizers and the bridge networks which combine the directional filters. The main purpose of the bridges, however, is to reduce the severe harmonic requirement on the directional filters due to having high- and low-level signals present at the repeater terminals. The whole carrier circuit is designed on a nominal impedance of 55 ohms. Attached to the *B*-end of the repeater is the loop-gain supervisory unit and also, via a high-voltage fuse, a moisture-detector unit which is used primarily during the high-pressure test to confirm that the housing is free from leaks. The latter comprises a series-resonant circuit at about 1.3 mc (megacycles), in which the inductance is varied by the gas pressure on an aneroid capsule mounted in the space between the electrical unit and the housing. The presence of moisture in this cavity increases the gas pressure owing to the release of hydrogen by the reaction of water vapor with metallic calcium held in a special container. At a later stage, the fuse is blown to disconnect this circuit.

The circuit design of the repeater introduces multiple-shunt paths across the amplifier, and care has to be taken to ensure that there is adequate attenuation in each path. In general, the design is such that the combination will give a loop loss of a least 40 db in the working band (to reduce rolls in the gain characteristic) and 20 db at all frequencies (as a guard against instability), even when one repeater terminal is open- or short-circuited to simulate a faulty cable.

UNIT DETAILS

Power Filter

The power filters are in effect a series pair of high- and low-pass filters (see Fig. 2). The shunt capacitors may have to withstand 3 kv, and clearances on the input cable and some wiring have to be adequate for this voltage. The inductors have to carry the line current of 316-ma d-c, and the intermodulation must be extremely low (see section on inductors).

Directional Filter

The directional filters are a conventional Zobel high-pass and low-pass filter pair with a susceptance-annulling network. Silvered-mica capacitors and carbonyl-iron dust-cored inductors are used. The bridges combining the "go" and "return" filters reduce the distortion, caused by the ferromagnetic material, to an acceptable level.

Bridge and Equalizer

A simple nonresonant bridge is used at the *B*-end of the repeater, but the *A*-end bridge is a resonant type and provides a substantial degree of equalization (see Fig. 2).

The equalizers are of conventional form. Trimming capacitors (selected on test) were provided for critical capacitances in order to utilize standard tolerances on all capacitors. A pad of 0.2 db and 0.4 db is provided on each equalizer unit, so that the repeater low-frequency or high-frequency path can be independently trimmed to give the best match to the target response for the repeater.

The components in this circuit were small air-cored inductors, silvered-mica capacitors, and wire-wound resistors, except for a few high-resistance ones, which were of the carbon-rod type. Included in this unit are coaxial chokes which separate parts of the circuit to avoid the effect of multiple grounding. They are merely inductors wound with coaxial wire on 2-mil permalloy-C tape ring cores.

Supervisory Unit

The supervisory unit comprises a frequency-selection crystal filter of about 100-cycle bandwidth in the range of 260 to 264 kc, fed from the low-frequency output end of the repeater via a series resistor. This filter feeds a full-wave germanium point-contact crystal-rectifier bridge which acts as a frequency doubler. The second harmonic in the 520- to 528-kc band is filtered out by a coil-capacitory band-pass filter, and fed back through a resistor to the same point

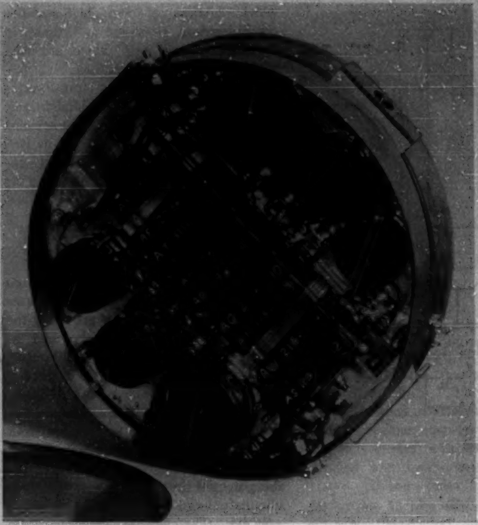

Fig. 4. Directional filter unit. High-pass filter with low-pass filter can on rear

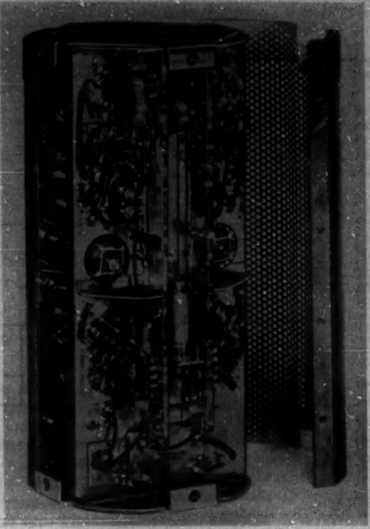

Fig. 5. Amplifier

in the repeater. The two series resistors minimize the bridging loss of the unit on the repeater and ensure that a faulty supervisory component has negligible effect on the normal working of the repeater.

D-C Path

The d-c path includes a resistor providing the 90-volt supply and the heater chain of six electron tubes (see Fig. 2). The voltage drop across the heater chain is not utilized for the amplifier high-voltage supply, as the heaters would then be at a positive potential with respect to the cathodes, thereby increasing the risk of breakdown of heater-cathode insulation. There would also be a complication in maintaining the constant heater current, particularly if the high-voltage supply current fail in one path of the amplifier. The normal amplifier high-voltage supply current is 32 ma.

It is essential to maintain a d-c path through the repeater even under fault conditions, in order that fault-location methods may be applied. Special care has therefore been taken to provide parallel paths capable of withstanding the full line current. For example, the high-voltage resistor actually consists of a parallel-series combination of ten resistors, and the whole assembly is supported on Sintox (sintered alumina) blocks which maintain a good insulation at 3-kv d-c, even at high temperatures.

Electron tube operation for consistent long life indicates the necessity of maintaining a specific constant cathode temperature; to achieve this, electron tubes are arranged according to heater characteristics into six heater-current groups between 259 and 274 ma and stabilized to ±1%. The appropriate heater-shunt resistor is applied so that the tube operates correctly with 316-ma line current, but for convenience the shunt is taken across each set of three tubes, all in one heater group, forming one amplifier path. *R*1 is fixed (300 ohms) and *R*2 is selected to suit the tubes. *R*1 is the resistance winding of a special short-circuiting fuse. When energized by the full line current should a heater become open-circuited, it causes a permanent direct short-circuit across the heater chain. The line voltage will be temporarily increased by about 95 volts while the fuse operates (1 minute) and will then drop to 12 volts below normal.

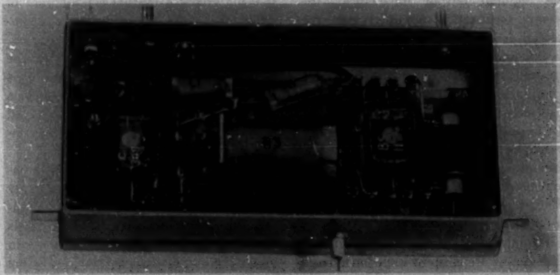

Fig. 6. Feedback unit of amplifier

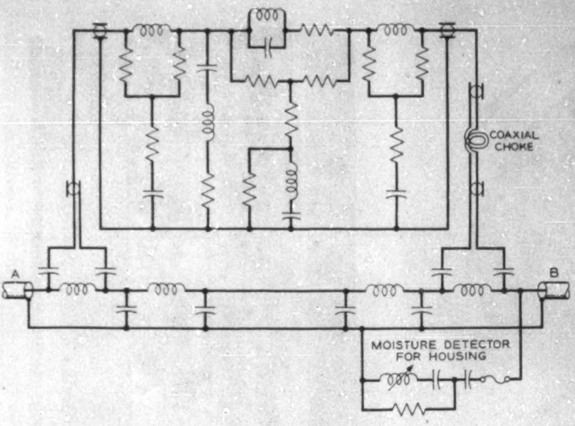

Fig. 7. Schematic of submerged equalizer

Amplifier

The amplifier circuit is shown in Fig. 3. It consists of two 3-stage amplifiers connected in parallel between common input and output transformers with a single feedback network. This circuit arrangement allows one amplifier path to fail without appreciably affecting the gain of the complete amplifier (less than 0.1 db for all faults except those on the grid of *V*1 and the anode of *V*3), but the overload point is reduced by about 5 db and distortion at a given output level is increased (about 12 db for second harmonics). Care has been taken to ensure that the open- or short-circuiting of a component in one amplifier path will not affect the performance, life, or stability of the remaining path, and this involves the duplication of certain components.

Mixed feedback is employed to produce the required output impedance; the current feedback is obtained from the resistor feeding the high-voltage supply to the output transformer, and the voltage feedback is developed across a 2-turn winding on the output transformer, which also serves as a screen. The output of the feedback network is fed in series with the input signal to the grid of *V*1. The gain response of the amplifier is chiefly controlled by the series-arm components in the feedback network, which resonate at 600 kc.

The input transformer is built out as a filter and it steps up in impedance from 55 ohms to 17,000 ohms. Protective impedances minimize the effect of a short-circuit on the grid of one of the first-stage tubes. The anode load of the first stage resonates at 600 kc, and is roughly the inverse of the feedback network, giving constant feedback loop gain over the working frequency band. The output tube has about 5.5 db of feedback from its cathode resistor, and the pair of output tubes feeds the output transformer, which steps down from 5,000 ohms to 55 ohms.

Specially designed, long-life tubes are used.[7] The first two stages are operated at about 40 volts on the screens and anodes; each anode current is 3 ma, giving a mutual conductance of 5.1 ma per volt. The output stage is operated at 60 volts on the screen, at +15 volts on the suppressor grid to sharpen the knee of the V_a/I_a characteristic, and at nearly the full high-voltage supply of 90 volts on the anode; the anode current is 6 ma giving a mutual conductance of 6.6 ma per volt. The tube dynamic impedance is approximately 300,000 ohms. To obtain an anode current nearest to the design value (and one for which the tubes are aged), one of two values of bias resistance can be selected for *V*1 and *V*2, and one of three values of bias resistance for *V*3.

All capacitors subject to the high-voltage supply are of the oil-filled paper type, and the others are of the silvered-mica type. Inductors are air-cored spools which are multisectioned when used in high-impedance circuits. All resistors are of the solid carbon-rod type, except for the input-transformer termination, which consists of two high-stability cracked-carbon resistors, and those in the feedback network, which are wire wound.

The input and output transformers employ 2-mil permalloy-C laminations, and the latter core is gapped on account of the polarizing current. A narrow Perspex spool fits the center limb, and conventional layer windings are used; the screen is a sandwich made of copper foil and adhesive polythene tape.

MECHANICAL DESIGN DETAILS

The general arrangement may be seen in Fig. 1. At the *A*-end is a cast-brass pot containing the resistors providing the amplifier high-voltage supply, and as this is bolted directly on to the housing bulkhead, the heat generated is readily conducted away. The remaining units are in cylindrical cans mounted in the insulating framework formed by four Perspex bars. These are sprayed with copper on both faces to guarantee the d-c potential on these surfaces and they eliminate the risk of ionization at working voltages. The cans are not hermetically sealed but are dried out with the repeater when it is finally sealed and filled with dry nitrogen. Perforated covers on the amplifier allow air circulation to reduce the ambient temperature.

Fig. 4 shows a typical can assembly, and Figs. 5 and 6 the construction of the amplifier. It will be seen that the latter is a double-shelved structure with tubes alternating in direction, and an amplifier path located on each side of the chassis; the input and output transformers are at opposite ends, and the feedback network is contained in a hermetically sealed can in the center of the unit.

All cans are finished with a gold flash which is inert and, giving a clean appearance, stimulates a high standard of workmanship. Tin plating was formerly used, but it has been shown that tin tends to grow metallic whiskers.[8] Unfortunately, certain capacitor cans had to be tin plated, which necessitated extra precautions in wide clearances or protective shields. The risks from growth on soldered surfaces are not thought to be great, as all solders used have less tin content than the electric alloy. Gold plating is used for all connecting wires instead of the usual tin plating.

The insulating subpanels in units are usually made of Perspex, but where the items are subjected to high temperatures (e.g., the resistance box), Sintox, a sintered alumina ceramic, or Micalex, is used.

Polytetrafluoroethylene (ptfe) is another insulant used, and ptfe-covered

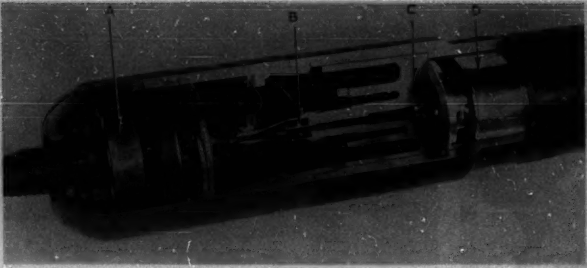

Fig. 8. Details of housing construction

A—Armor clamp B—Gland C—Bulkhead D—Part of internal unit

wire, threaded through copper tubing forms the coaxial interconnecting leads between the can units.

Careful attention is paid to the mounting of components. Small resistors, etc., are supported by soldering to tags which are the appropriate distances apart, and multilimb tags are employed to minimize the number of soldered joints. Where it is essential to solder more than one wire per limb on a tag, they must be soldered at the same time. Larger components are clamped. Electron tubes are mounted in a holder to facilitate preliminary testing with "standard electron tubes," and they have a sprung-nylon retainer; the final electrical connection is made by soldering on to an extension of the wire leading through the pins.

Design of Internal Unit of Submerged Equalizer

The submerged equalizer corrects for the difference between the assumed design cable characteristic and the subsequently determined laid characteristic for equal attenuation lengths at 552 kc. It also absorbs the loss of 9 nautical miles of cable and has an attenuation of 26.0 db at 552 kc.

The construction is identical with the submerged repeater except for the replacement of all can assemblies, other than the power filters, by the equalizer cans. Fig. 7 is a schematic of the unit.

Electrical Components

GENERAL

The components used in the repeaters were either designed specially for submerged repeaters or were standard items with improvements. There are approximately 300 components in each repeater, of which 110 are in the amplifier. Rigorous control of manufacture and meticulous inspection are imperative to ensure a consistent long-life product, and cleanliness is essential at all stages. In some cases "belt-and-braces" techniques can be effectively employed, e.g., by using double connections. Over 1,500 separate soft-soldered connections are involved in the complete assembly. Much work has been done on components, but only a brief indication can be included here. A range of typical components appears in Figs. 4–6.

RESISTORS

Resistors fall into the following categories:

1. Power resistors used solely for d-c purposes (e.g., resistors providing the amplifier high-voltage supply). These are wire-wound vitreous-enamelled resistors on Sintox ceramic formers. Nichrome terminal leads are used, and all connections are brazed.

2. High-frequency resistors, whose tolerance is not close, and which often carry direct current but of low power (e.g., anode load resistances). A modification of a standard carbon-rod resistor is used. The ends of the rod are copper plated and the end caps and terminal leads are soldered on. The tolerance is normally ±5%, and the maximum rating permitted is about one quarter of the commercial rating.

3. Precise high-frequency resistors of resistance below 1,000 ohms (e.g., feedback components). Here wire-wound spool resistors are suitable, and bifilar or reverse layer windings with Lewmex enamel and silk-covered wire are used.

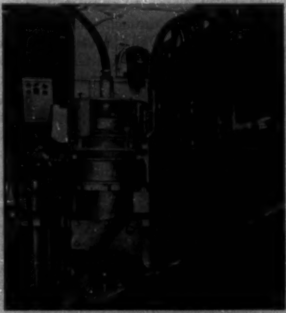
4. Precise high-frequency resistors of high resistance. For terminating the input transformer a resistance of 17,000 ohms is required. Because it is not possible to make a suitable wire-wound resistor, high-stability cracked-carbon film resistors are used, but to minimize the effect of a disconnection two are used in parallel.

INDUCTORS

The majority of inductors used in the amplifier and equalizer do not require a high Q-factor. They are wound on air-cored ceramic bobbins of four types, and the high-inductance ones are sectionalized. In general, solid wire with Lewmex enamel and double-silk covering is used for the amplifier inductors, and stranded wire for the equalizer inductors.

A high Q-factor inductor is essential in the directional filters, and a carbonyl-iron pot core was used; the Q-factor is about 250 at 300 kc. Precise adjustment and stability of inductance were obtained by setting the gap between the halves of the pot core with a cement of Araldite (an epoxy resin) and titanium dioxide. A Perspex former was used.

Special inductors were required in the power filters to take the 316-ma d-c line current. A wave-wound air-cored coil was used for the carrier-path filter (L_1 in Fig. 2), and a toroid on an audio-frequency Permalloy dust-core ring was used for the low-pass filter (L_2 in Fig. 2). Solid wire, with Lewmex and double-silk covering, was used to keep the d-c resistance to a minimum.



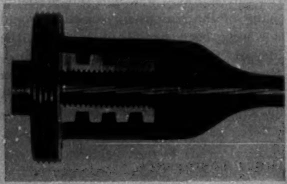


Fig. 9 (left). Silver-soldering of bulkhead into housing with induction heater

Fig. 10 (above). Section of high-pressure gland

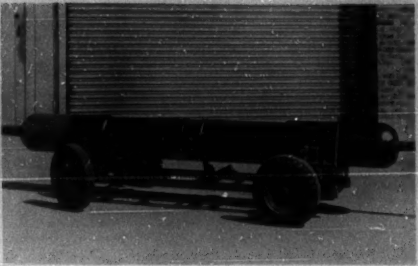

Fig. 11 (left). Coil production in the "dairy"

Fig. 12 (above). Completed repeater

CAPACITORS

Capacitors are divided into three categories:

1. Those subjected to the full line voltage which may operate at up to 3 kv.
2. Those subjected to the amplifier high-voltage supply of 90 volts.
3. Those which have negligible polarization (less than 10 volts), and which are often required to precise values.

Categories 1 and 2 are of the oil-filled paper type, with respectively four layers of 36-micron and three layers of 7-micron kraft paper. The oil is a mineral type loaded with 18% resin, and the capacitors are filled at 60 C and sealed at room temperature.

Small capacitors and those of precise value as in category 3 are silvered-mica capacitors. These are encased in an epoxy resin to give mechanical protection and a seal against moisture. Visual inspection of all mica plates is made before and after silvering, and any with cracks, inclusions, stains, or any other abnormality are rejected. Mica is a very variable material and at times the percentage of rejects was high, but probably many of the reasons for rejection would not have been significant as far as the life of the capacitor was concerned. However, experience has shown that even with stringent precautions mica is not an entirely satisfactory dielectric material.

OTHER COMPONENTS

Electron tubes form the subject of a separate paper.[7] Of the other miscellaneous components used, one of interest is the short-circuiting fuse across the electron tube heaters. Its construction is like that of a normal wire-wound resistor on a Sintox tube former, but inside are two cupped copper electrodes filled with a low-melting-point eutectic alloy. If the full line current (316 ma) is passed through the winding, owing to a heater disconnection, the heat generated is sufficient to melt the alloy, which then fuses the two electrodes together. The winding is thus short-circuited, and a permanent connection is left between the electrodes.

Design of Housing and Gland

GENERAL

Although the maximum depth of the water in which British rigid-type repeaters were laid did not exceed about 250 fathoms, the housings used for these repeaters were generally of a type designed for use at ocean depths, and when connected into the cable they were amply strong enough to transmit stress up to the breaking point of any of the cables used.

The part of the housing which is sealed against water pressure consists essentially of a hollow cylinder, machined from hot-drawn steel tube, and closed at both ends by steel bulkheads carrying the cable glands, through which the connections are made to the electrical unit (see Fig. 8). The latter is bolted rigidly to the inner face of the *A*-end bulkhead. The steel blanks used for the main cylinder and the bulkheads are tested with an ultrasonic crack detector, and after machining they are further subjected to magnetic crack-detection tests.

Each gland has a brass cover which completes the coaxial transmission path and contains a weak solid mixture of polythene and polyisobutylene (pib). Outside the brass cover is a larger chamber closed by a flexible polyvinylchloride (pvc) diaphragm and containing pib, a viscous liquid, which prevents sea water from coming into direct contact with the bulkhead seal and the gland assembly.

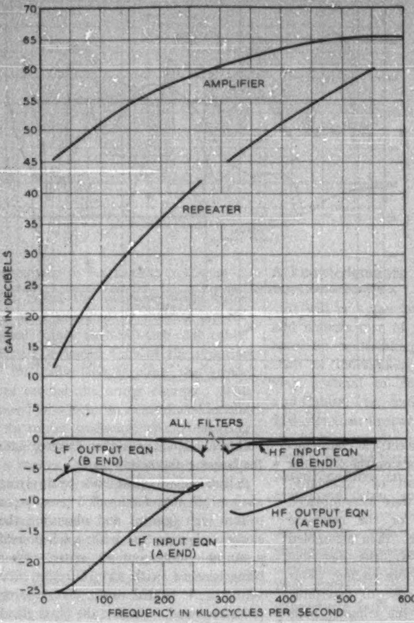
Cylindrical extension pieces, screwed on to the main casing, contain the clamps for attaching the repeater housing to the armor wires of the sea cable, and the housing is completed by dome-shaped end covers. Two external annular ridges near the center of the housing accommodate the special quick-release clamp used for handling the repeater during the laying operation.

Protection against corrosion is provided by shot-blasting the surface and then applying hot-sprayed zinc to a thickness of 0.010 inch, followed by two coats of vinyl paint. The *A*-end of the repeater is finished in red. The dimensions of the complete repeater are 8 feet $11^{3}/_{8}$ inches by $10^{1}/_{2}$ inches in diameter, and its weight is 1,150 pounds in air.

SEALING OF HOUSING

The bulkheads, which register on seatings designed to withstand the axial thrust from the water pressure, are in the form of disks with extended skirts. A watertight and diffusion-proof seal is formed between the casing and the outer skirt of each bulkhead by a silver-soldering process, with the use of carefully controlled electromagnetic induction heating to raise the jointing region to the required temperature. The diametral clearance between the cylinder and the locating surface of the bulkhead is 0.003 ±0.002 inch, the diameter of the bulkhead being reduced by 0.004 inch for an axial distance of 3 inches from the rim of the skirt to provide a recess into which the molten solder can flow.

The solder is applied as eight preformed No. 16 standard wire gauge wire rings



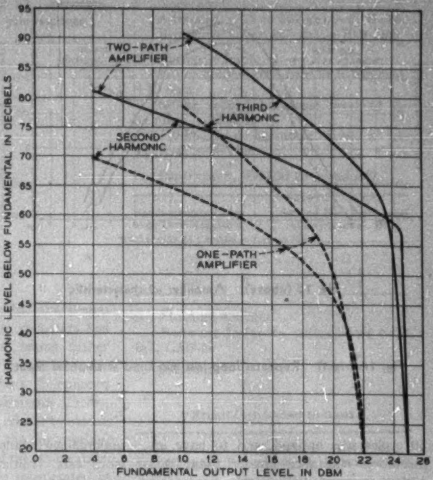


Fig. 13 (left). Repeater gains and losses

Fig. 14 (above). Amplifier distortion

which are fitted into place when cold, and coated with a paste formed by mixing flux powder with dehydrated ethyl alcohol. The generator used for heating has a nominal output of 50 kw at a frequency of about 350 kc and is capable of raising the temperature of the jointing region to 750 C in 5 minutes. The temperature, as indicated by four thermocouples inserted in special holes drilled in the ends of the casing, is maintained at 750 C for a period of 45 minutes to allow ample time for the entrapped gas and flux pockets to float to the surface. Fig. 9 shows the arrangement for soldering in a bulkhead.

The primary object of the outer skirt is to keep the heated region far enough away from the base to prevent the temperature of the latter from rising unduly. Temporary water jackets are also clamped over the gland and around the outside of the casing during the sealing operation. A subsidiary skirt on each bulkhead contains a vent hole which serves to allow displaced air to escape as the bulkheads are inserted into the casing. These vents are later used to apply a low-pressure gas-leak test to the bulkhead seals, and then to flush the housing with dry nitrogen to remove any trapped moisture. The vents are finally sealed. At this stage, the sealed housing is pressure-tested in water at $1\frac{1}{2}$ long tons per square inch for a period of 7 days, a moisture detector (mentioned previously) being used to check the leakage. (One long ton = 2,240 pounds.)

Glands

The deep-sea gland was developed from the castellated gland which has been used successfully for a number of years in shallow-water repeaters. The basic principle of this gland is very simple and is shown in Fig. 10; the polythene-insulated cable core passes right through the bulkhead, and the initial seal is formed by the contraction, during cooling, of polythene molded on to the core and enclosing a steel stem, having a castellated profile, forming part of the bulkhead. Each side of the castellation has a taper of about 7 degrees. The application of water pressure increases the contact pressure between the polythene and the stem, making the gland inherently self-sealing. As an additional safeguard, the gland stem is first prepared by a lead plating and anodizing process, followed by the application of a thin film of polythene which forms a chemical bond to the plated surface. The injected polythene merges with this film, thus bonding the molded portion to the castellated stem. Tests on sample glands, with radioactive tracer, have shown no measurable) water diffusion (less than 0.001 milligram) at a pressure of 5 long tons per square inch over a period of 6 months.

Intrusion of the polythene into the housing, at hydraulic pressures up to at least 6 long tons per square inch, is eliminated by the use of a small-diameter core and by the provision of a screw thread in the hole through which the core passes. During the molding operation a corresponding thread is formed on the polythene core itself. This method of construction distributes the axial force over a sufficiently wide area to prevent any appreciable creep of the polythene.

The completed gland assemblies were all subjected to a minute X-ray examination, followed by a pressure test at 5 long tons per square inch for 3 months. While under pressure, the glands had to withstand a voltage test of 40 kv d-c for one minute, to show no ionization effects when a voltage of 3 kv (rms) at

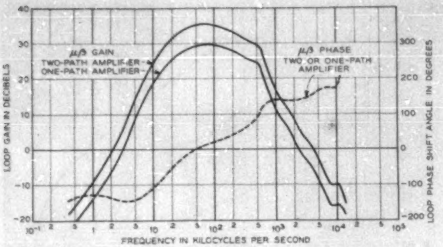

Fig. 15 (above). Amplifier $\mu\beta$ characteristic

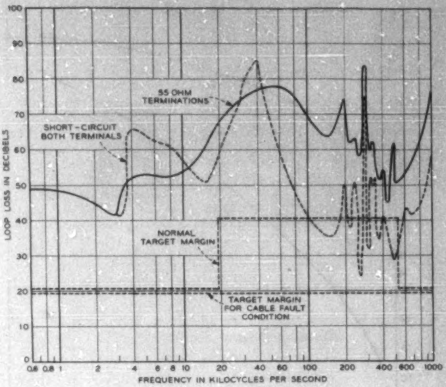

Fig. 16 (right). Repeater loop-loss measured at amplifier input

50 cycles was applied, and to have an insulation resistance greater than 20×10^{12} ohms.

Manufacture

General

The manufacture of the electrical units was carried out in accommodation specifically designed for submerged-repeater production. Temperature was controlled at 68 F (degrees Fahrenheit) and the relative humidity was less than 20% in the component shops and 40% in the assembly and test shops. Filtered air forced into the building maintained a slight positive pressure with respect to the outside and eliminated the ingress of dust. With the exception of the tubes and some resistors, all components were manufactured in this "dairy" (see Fig. 11). Operators are specially selected, and they must change into clean protective clothing in an anteroom before entering the working area, where no smoking or eating is permitted. All operators are particularly encouraged to report or reject any condition which is abnormal or in which they have not complete confidence. Rigorous inspection and testing were carried out by the contractor at all stages, and a Post Office team collaborated with "floor" inspection and the examination and approval of test results.

The Electrical Unit

The components, after the most careful examination and testing (which in some cases included an aging test), were assembled into their cans and then subjected to a shock test before undergoing detailed electrical-characteristics tests. Initial tests on the amplifier were done with a set of "standard" electron tubes, which were later replaced by the final tubes for the complete tests. The cans were then assembled in a repeater chassis; the electrical tests were required before sealing. This included a gain response to determine the best settings for the trimmer pads in each transmission band. After fitting and sealing the outer brass case, dry nitrogen was blown through the unit for 24 hours, then the gas holes were sealed. The over-all electrical characteristics were then taken, the repeater was energized for a 2-week "confidence trial" and the characteristics were rechecked. During the confidence trial, the gain was continuously monitored on a recorder (duplicated to distinguish between test equipment and repeater variations) on which changes in gain of 0.01 db were clearly indicated. On satisfactory completion of these tests the unit was ready for housing.

Assembly of Electrical Unit in Housing

The first step was to complete the molded joint between the tail cables from the *A*-end of the electrical unit and the low-pressure side of the appropriate bulkhead. This joint was X-rayed and proof-tested at 20 kv d-c for 1 minute. The electrical unit was then bolted to the bulkhead, the slack tail cable being correctly coiled into the recess provided, and the whole assembly was lowered into the housing for the first silver-soldering operation. Following this sealing, the tail cable joint was made to the *B*-end bulkhead, which was then lowered into the housing and sealed.

A leak test was then made by applying an internal air pressure of 5 pounds per square inch (gauge) and observing the surface when wetted with a solution of a suitable detergent in water. After being flushed with dry nitrogen, the vents were sealed and the housing pressure-tested. Finally, the brass gland covers were fitted and filled with compound, the extension pieces were screwed on, the flexible diaphragms were fitted, and the internal space was filled with polyisobutylene. The housing was then ready for further electrical testing.

Tests on Complete Repeater

After housing, the repeaters were submerged in a tank of water for a 3-month electrical confidence trial. Before and after the trial, the complete characteristics were checked and the noise was monitored on both terminals; during the first and last few weeks of the trial the gain was monitored on recorders in both directions. Owing to the insertion and withdrawal of repeaters in the power circuit from time to time, the repeaters were subjected to several power-switching operations and temperature cycles.

Stability of electrical characteristics, particularly gain, between the prehousing tests and the completion of the confidence trial some 4 months later was regarded as an important criterion of the reliability of a repeater. Unfortunately, test conditions, in addition to differences between and stability of the testing equipments, reduced the accuracy originally expected; nevertheless, changes of over 0.1 db were regarded as significant.

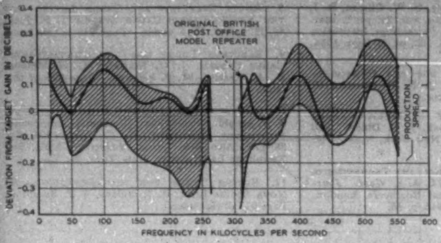

Fig. 17. Repeater-gain response

CONNECTION OF REPEATERS TO CABLE

On board the cable ship the cable ends were prepared by making tapered molded joints to 0.310-inch tail cable, sliding the domed ends of the repeater up the cable and forming the armor wires around the armor clamps. The tapered joint included a castellated ferrule on the center conductor, which, operating on the principle of the main gland, acts as a barrier against the possible passage of water down the center conductor into the repeater. The final assembly operation consists of jointing the tail cables, bolting the armor clamps to the repeater housing, and screwing on the domed ends. Fig. 12 shows a completed repeater connected to a cable.

Performance

The gains and losses of various sections of the repeater are shown in Fig. 13. Figs. 14 and 15 show respectively the harmonic distortion and the stability characteristics of the amplifier with one and two paths operating. The total shunt loss across the amplifier is shown in Fig. 16, as a margin above the amplifier gain. The curves show the result with 55-ohm terminations on the repeater and with a short circuit on each terminal. Fig. 17 shows the production spread in gain of the 16 repeaters for the system as a deviation from the target value. The highest standard deviation (at 260 kc) was only 0.11 db. In all respects the production repeaters proved to be very consistent and satisfactory in their performance, and differed little from the original laboratory-built model. Typical electrical characteristics of a repeater and the submerged equalizer are shown in Appendixes I and II respectively.

The characteristics of the completed link are described elsewhere,[9] but it is of interest that the over-all tests showed that the link behaved as predicted and met the noise requirement and the design margins.

Acknowledgments

It will be appreciated that the design and manufacture of these repeaters has been an undertaking of teams rather than of individuals. The authors are very grateful to Standard Telephones and Cables, Ltd., and Submarine Cables, Ltd., for their unsparing efforts to ensure the highest standards in the engineering, production, and testing of these repeaters. Numerous firms have also co-operated in specialized fields, and the authors are very appreciative of their help. The authors also wish to acknowledge the enthusiastic assistance of their many colleagues in the Research Branch of the Post Office in the design and in the supervisory inspection during manufacture. Finally a grateful acknowledgment is made to the engineer-in-chief of the British Post Office for permission to publish the paper.

Power-Feed System for the Newfoundland–Nova Scotia Link

J. F. P. THOMAS   R. KELLY

Synopsis: Design engineers now have available the results of many years of operating experience of submerged-repeater systems supplied from electronic, electromagnetic, and rotary-machine power equipments. To meet the unusually high standards of reliability required for the transatlantic telephone system, a scheme has been evolved that is a combination of new developments and the best features of previous methods. Electronic electromagnetic equipment forms the basis of an automatic no-break system requiring little routine maintenance.

THE OPERATING power for the submerged repeaters of the Clarenville–Sydney Mines link is derived from a constant current supplied over the central conductor from power equipments located at the two terminal stations. To protect the electron tubes in the repeaters, the current must be closely maintained at the design value, irrespective of changes in the main supply voltage or ground potential differences between the two ends of the link. Automatic tripping equipment must be provided to disconnect the cable supply should the current deviate beyond safe limits, but otherwise there must be a minimum of interruptions due to power-equipment and primary-source failures.

Earlier British Post Office schemes have been powered by electronically controlled units feeding from one end only.[1] Manual changeover to stand-by units has been provided at the end feeding power and at the distant end, a method which has satisfactorily met the economic requirements of short schemes.

For the Clarenville–Sydney Mines link a new and more reliable design of equipment has been developed. An automatic no-break system provides an uninterrupted supply to repeaters unless equipments at both ends of the link simultaneously fail to deliver power.

The main improvement in the reliability of the equipment is the replacement of all high-power electron tubes by electromagnetic components. The automatic no-break system takes advantage of the fact that the rating of the repeater-isolating capacitors has been chosen to permit single-end feeding. Normally the link is fed from both ends, but in the event of one equipment failing to deliver power the link is powered from the other end without interruption to the cable supply. If the failure is due to a power-equipment fault, double-end feeding can rapidly be re-established by manual switching to the stand-by. During an a-c supply failure, single-end feeding must be maintained until the supply is restored. In view of the very reliable no-break a-c supply provided at both stations, the possibility of a simultaneous a-c supply failure at both ends of the link is extremely remote.

The power equipments at each end of the link must be capable of supplying the whole of the power to the cable, should one end fail, which requires that each should be capable of operating as a constant-current generator. If two constant-current generators are connected in series, unless precautions are taken, an unstable combination will result and the unit supplying the higher current will drive the other unit "off load." Manual adjustment could be provided to equalize the currents fed from the two ends, but a different solution has been developed in which one of the units is a constant-current master and controls the line current, while the other unit is a slave whose voltage-current characteristic in the normal operating range is such that its current is always equal to that of the master unit. If the slave unit fails, the master will take over the supply; if the master unit fails, the slave unit will take over the supply and automatically assume the role of a master unit. The first unit switched on to an unenergized link operates as a master generator and the other unit, on being switched on, automatically operates as a slave. Other than ensuring that the link is safe for energizing, there is no need for any co-operation between the two ends when putting the equipment into service.

Details of Method Employed

MASTER-SLAVE SYSTEM OF OPERATIONS

The output-current output-voltage characteristics for the equipments are shown in Fig. 1, and are the same for both regular and alternate equipments at both ends of the link. Any equipment can operate with any of the characteristics *a*, *b*, or *c*, Fig. 1.

Normally the choice between characteristics *a* and *b* is made automatically by the equipment. If the output voltage does not reach 80% (per cent) of the full link voltage (approximately 2 kv), the unit will have the slave characteristic *b* (*DCAB* in Fig. 1). If the output voltage reaches or exceeds 2 kv, the unit automatically switches to the master characteristic *a*, (*EAF* in Fig. 1). Once having switched to the master characteristic

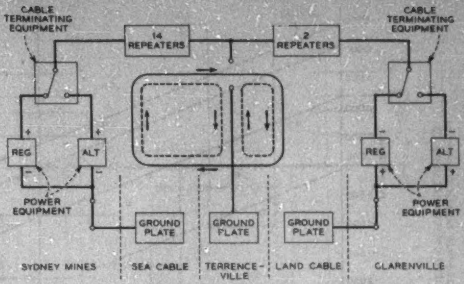

Fig. 2. Current paths on Clarenville–Sydney Mines link

the equipment does not automatically change back to the slave characteristic even when the output voltage falls below 2 kv.

When the link is energized, the first equipment switched to line will come on as a slave unit; its output voltage will then pass 2 kv and it will automatically be switched to the master characteristics and the complete link will be energized from one end. The second unit switched to line will come on as a slave unit and, having a higher output current, will drive down the output voltage of the master unit at the other end until the current of the slave unit has become equal to that of the master; see *DCA* in Fig. 1. The output voltage of this equipment will not exceed 2 kv and it will not switch to master. The crossover point of the two characteristics *A* will determine the potential fed from each end, and this can be adjusted as indicated by the dashed lines near *C*.

In an emergency, an equipment can be taken out of service by switching off the a-c supply, and the links will then be powered from the distant end only. Should the master end be switched off, the distant slave unit will switch to master characteristic as soon as its output voltage exceeds 2 kv. This abrupt disconnection of one equipment causes unnecessary voltage surges on the cable, and when an equipment is removed for normal maintenance purposes, the following procedure is adopted. The slave equipment is switched to the master characteristic by means of an external key for changing from master to slave or vice versa. (Its limitation is described in the next paragraph.) This leaves two master equipments feeding the cable, but any redistribution of voltage is slow since the currents are approximately equal. An external control (master/master shut-down), is then operated on the equipment to be taken out of service, changing its characteristic to that shown as *c* in Fig. 1. The output voltage of this unit will then be slowly reduced, and when it is zero the equipment can be switched off without causing surges on the cable.

The current deviations occurring over the slave characteristics, *c* in Fig. 1 (from +2% to −3%) are the maximum permitted by the tube design engineers for the tubes in the submerged repeaters, and are permitted only for short periods. The circuit associated with the manual switching of the equipment to the slave characteristic is therefore made inoperative if the output voltage exceeds 2 kv, since in this range the slave characteristic is the extension of the line *CAB* on curve *b* and the current is outside the permitted range. The slave characteristic over the range *CAB* is controlled by a voltage-sensitive circuit connected near the output of the equipment, and the stability of the characteristic against input voltage and component aging is the same as for the master characteristic. Changes in the distribution of the system potential due to supply variations and component aging are therefore small.

Over-all Current and Voltage Distribution

Facilities have been provided at the junction of the land and sea cables (Terrenceville) to connect a power ground to the center conductor of the cable. Normally this ground will be disconnected, but during installation it enables the land and sea sections to be energized separately and may subsequently be of assistance in the localization of cable faults near Terrenceville.

The full line in Fig. 2 shows the current path with normal double-end feeding, while the broken lines show the current paths when a ground is connected at Terrenceville.

The full line in Fig. 3 shows the voltage distribution along the link with normal double-end feeding, the broken lines *a* and *b* show the distribution with single-end feeding from Sydney Mines and Clarenville respectively, and the broken line *c* shows the distribution when a power ground is connected at Terrenceville.

Details of Equipments

Connection of Equipment to Cable

Each station is provided with two power equipments and one cable-terminating equipment interconnected as shown in Fig. 4. When the live side of the output of the regular equipment is connected to the cable via *SWD* and the link *LK1*, the alternate equipment output is connected to its own dummy load (equivalent of *RV1*) and vice versa.

The grounded sides of the regular and alternate equipments are common, and then connected via a removable link *LK2* to the sea ground. A safety resistor *R2* connects the sea ground to the station ground to restrict the rise in potential to 100 volts if the sea ground becomes disconnected. During maintenance on the sea-ground circuit the link *LK2* can connect the power-equipment ground to the station ground.

If, for maintenance purposes, it is necessary to feed from the distant end only, the link *LK1* can connect the cable to the power-equipment ground and, in addition, disconnect the live side of both of the power equipments from the line.

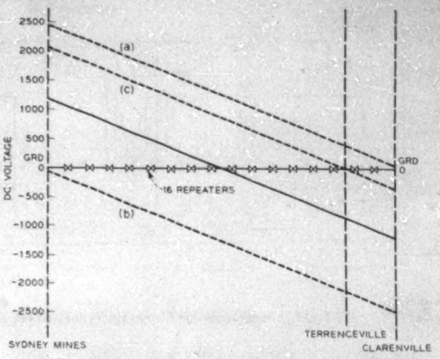

Fig. 3. Potential distribution on Clarenville–Sydney Mines link. (a)—Single-end feeding from Sydney Mines. (b)—Single-end feeding from Clarenville. (c)—Ground at Terrenceville; double-end feeding. (d)—Normal operation; double-end feeding

SAFETY INTERLOCKS

Safety interlock circuits are installed to protect the maintenance staff if the equipments are used incorrectly and are not the normal methods employed for controlling the power supplies. With double-end feeding, dangerous voltages are generated at both ends of the system, and when access is gained to any point in the equipments, personnel must be protected from the local and distant power sources.

To minimize interruptions to traffic, the units of the cable-terminating equipment are grouped under three headings, Fig. 4, namely:

1. Transmission equipment *S1* isolated from the d-c cable supply: this includes cable simulators and monitoring facilities not associated with the power supplies.
2. Equipment associated with the d-c supply that can be made safe without interrupting traffic.
3. Equipment that can be made safe only by interrupting traffic.

Group 1 is treated as normal terminal transmission equipment and is not interlocked. Groups 2 and 3, the power-changeover and cable-terminating boxes respectively, both require that the local power equipments be switched off before they can be made safe. The external panel-covers over both boxes have links disconnecting the a-c supplies to both of the local power equipments when the covers are removed, *LK3-LK6*. This will not interrupt traffic, since single-end feeding will continue from the distant station.

The doorknob switch of the power-changeover box automatically connects the live lead to ground at point *B*, when the door is opened. This will not interrupt traffic since the impedance of *L2* is high at carrier frequencies. Changing over the power equipments and grounding arrangements can therefore be performed without interrupting traffic.

The doorknob switch of the cable-terminating box automatically connects the center conductor of the cable to ground, at point *A*, when the door is opened. Traffic will therefore be interrupted if maintenance work is necessary within this box.

Access is gained to a power equipment by opening one or more of four doors. Each of the doorknob switches disconnects the a-c supply (*SWA*) and short-circuits the output of the equipment, *SWC*.

It will be appreciated that if the correct procedure is adopted the local power equipments will be switched off by *SWB* after the master/master shut-down procedure (described in the section "Master-Slave System of Operations," has been carried out, and not by removing the panel covers or opening the doors.

ELECTRICAL DETAILS OF POWER EQUIPMENT

Control Method

Fig. 5 is a functional simplified circuit diagram in which *TR1*, *MR1*, and *C1* represent a conventional unregulated power unit.

The control circuit compares a signal proportional to the output current V_0 with a stable reference signal V_R, the two signals being applied to the cathode and grid respectively of *V5;* the difference between them is amplified and used to adjust the voltage fed to the rectifier circuit *MR1*, to maintain the output current constant.

Ignoring at this stage the auxiliary coil *1–2* of the magnetically controlled diode *V3*, the output current flows through the coil *3–4* and controls the voltage across *R4* and hence, via the cathode-follower *V4*, the potential V_0 on the cathode of *V5*. V_R is a function of the output of a conventional electronic constant-voltage power unit (reference power unit) using a neon tube for its reference. The grid-cathode bias of *V5* controls the secondary impedance of the transductor *TD2* via the amplifier *V5*, *V6*, *TD1*. The gain of the control amplifier and the sign and magnitude of the normal impedance of the secondary of *TD2* are arranged to give a fall of approximately 0.25% in the current from full system load to short circuit.

Two advantages are obtained by employing a magnetically controlled diode for *V3* instead of an electrostatically controlled tube. The control is directly proportional to the output current, and is not dependent upon the stability of a series resistor, while the control circuits are isolated from the output-circuit voltage, which simplifies maintenance of the more complex parts of the equipment.

Current Characteristics

Without current flowing in the auxiliary coil *1-2*, on *V3* in Fig. 5, the equipment has a normal constant-current characteristic, the value of which, 322 ma (milliamperes), is preset by adjusting the mechanical position of the coil assembly along the main axis of *V3*.

Two neon tubes and two resistors form the bridge *V1*, *V2*, *R1*, and *R2*, which is balanced when the voltage drop across *R1* and *R2* equals the constant voltage across *V2* and *V1*, the output voltage at which this occurs being adjusted by *RV1*. At voltages below balance, current tries to flow from *y* to *x* and at voltages above balance it flows from *x* to *y*. The balance voltage corresponds to the voltage at which the slave-unit characteristic changes slope, *C* in Fig. 1. For voltages below balance the rectifier *MR2* prevents current from flowing in the winding *1-2* on *V3*, and in this range the constant current of 322 ma is maintained; see *DC*, Fig. 1. For voltages above balance, current flows in the winding *1-2* and

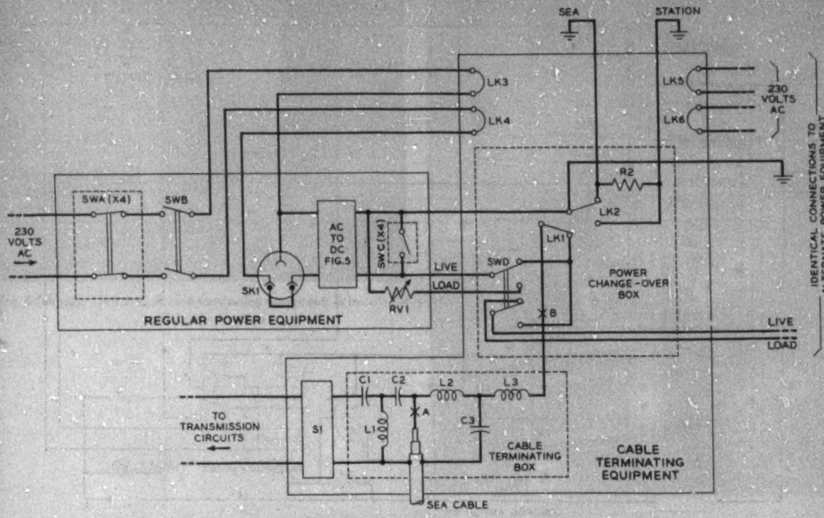

Fig. 4. Cable-terminating equipment and interconnections with power equipments

progressively decreases the output current *CAB*, Fig. 1. At 80% of the full link voltage, the contacts of relay *M* are operated and they disconnect the auxiliary coil *1-2* from the voltage-sensitive bridge and connect it across the reference supply. The current through *1-2* is then set by the fine current control *RV2* to make the output current the required 316 ma. As previously stated, relay *M* does not automatically switch back when the output voltage drops below 80 of full link voltage; the current characteristic of a master unit is *EAF* in Fig. 1.

The master/master shutdown characteristic, Fig. 1, curve *c*, is obtained by short-circuiting *R3*, which causes the constant current to fall to 312 ma. Adjusting *RV2* would be as effective, but short-circuiting *R3* does not permanently disturb the normal current setting.

Alarms

The equipment trips and gives both aural and visual alarms for +20% current +20% full link voltage and for the failure of certain auxiliary supplies that would damage the equipment.

Aural and visual alarms are provided for ±1.0% current and ±3% voltage, and for equipment changes from slave to master characteristic or vice versa. Visual indication is given if the a-c supply fails.

Reliability

Where possible, only components of proved integrity have been used. High-power thermionic tubes were excluded and the tube types employed were specially selected for long life. Electrolytic capacitors were excluded from all except one position, and in this case the component was divided into six units in parallel, the failure of all but one of these units causing only a slight increase in the output ripple.

Particular attention was given to the continuity of the output circuit. A failure of a power equipment for any reason other than an open-circuit in the output will not interrupt traffic, the system changing to single-end feeding from the far end. A disconnection anywhere in the d-c feed path will disconnect all power from the link. Relatively short-lived components in this part of the circuit were either duplicated in parallel or shunted by resistors capable of carrying the full line current.

Other Facilities

Each equipment has facilities for checking its over-all performance. A variable-ratio transformer can be introduced at *SK1*, Fig. 4, and, with the 4-position dummy load referred to earlier, the regulation against alternating input voltage and output load can be measured.

Provision is made for checking all the alarms, and the current can be measured at strategic points in the control circuit either when the equipment is normal or with the loop feedback disconnected.

Separate large-size meters are provided for measuring the output voltage and current to an accuracy of ±1.0%. A more accurate measurement of current is obtained from potentiometric measurements made across a standard resistor connected in series with the output.

ELECTRICAL DETAILS OF CABLE-TERMINATING EQUIPMENT

The majority of the electrical features of the cable-terminating equipment have already been considered.

Within the cable-terminating box, Fig. 4, are the power-separating filters; the high-pass filters *C1*, *C2*, and *L1* passing the carrier frequencies and the low-pass filter *L2* passing the direct current. The transmission equipment represented by the block *S1* is for convenience mounted in the cable-terminating cubicle. The extra low-pass filter *L3*, *C3* can be specially designed to prevent signals that are peculiar to the site (local radio stations, etc.), which are picked up in the power equipment, from being fed to the transmission circuits.

Metering facilities (not shown in Fig. 4) are provided to check the continuity

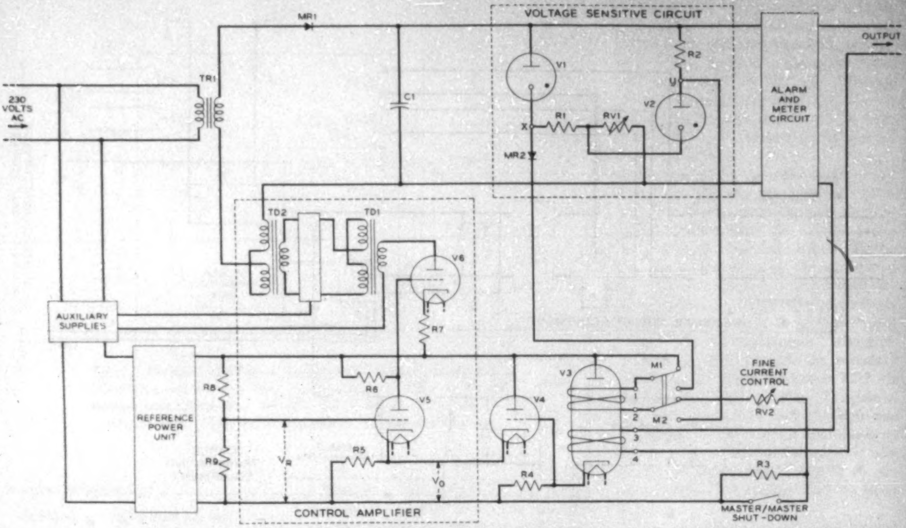

Fig. 5. Simplified schematic of power-feeding equipment

of the sea-ground circuit. A separate insulated wire is connected to the sea-ground plate and the continuity is checked by measuring the voltage drop along the ground cable. Aural and visual alarms are given if the sea ground becomes disconnected.

Current and Voltage Recorders

Current and voltage recorders are provided for both the regular and the alternate equipments, the values being measured at the points where the outputs of the power equipments enter the cable-terminating equipment.

A magnetic-amplifier unit drives the current recorder, the scale deflection being from −5% to +5% of the normal line current. The voltage recorder is connected across the ground end of a resistance potentiometer, the full-scale deflection being 3 kv.

The magnetic amplifier and potentiometer units are mounted in the cable-terminating equipment, but the four recorders and their associated supplies and alarms are mounted on a separate rack.

Mechanical Details

Fig. 6 shows two power equipments and a cable-terminating equipment as installed at each terminal station. The same cubicle frameworks are used for power and cable-terminating equipments, the power equipment consisting of two cubicles bolted side by side and fitted with doors at the front and back.

The top of the cable-terminating cubicle contains the power-changeover box and the center contains the cable-terminating box, while the transmission and ground-cable test circuits are located near the bottom. The main cable enters the bay at the top and passes behind the power-changeover box into the cable-terminating box. Access to the recorder units and cable simulators is from the rear.

Fig. 7 shows the front of one power equipment with the doors open. The left-hand cubicle contains the main high-voltage transformer, the electronic and magnetic parts of the control circuits, the reference power unit and the auxiliary supplies. The other cubicle contains the main rectifier and smoothing circuits, and the associated meter and alarm circuits.

Performance

Six power equipments and four cable-terminating equipments were manufactured for the link. Of these, four power equipments and two cable-terminating equipments were provided for the terminal stations and the remainder were for use on *HMTS Monarch* during the cable laying, and subsequently as off-station and training spares.

After individual testing, the power equipments were checked in pairs energizing a 16-section artificial cable constructed to simulate the Clarenville–Sydney Mines link. These tests were kept running for approximately 2 weeks on each equipment, and the line current was monitored with expanded-scale current recorders (from −1.0% to +1.0% of the normal current).

The equipments were completed early in 1956, and they have given satisfactory service both at the terminal stations and on board *HMTS Monarch*. From March to June 1956, all four units at the terminal stations were operating into their dummy loads and daily current and voltage readings were well within the required specifications. Since the laying of the sea section, the equipments have satisfactorily operated the completed link. When the link is in service, the working equipment at each end will be changed at 6-month periods and the changeover time will be staggered by 3 months each end. The equipment coming out of service will be immediately routine checked and adjusted if necessary.

The tests since installation confirm

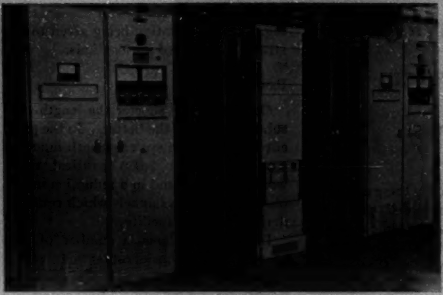

Fig. 6 (above). Power and cable-terminating equipments as installed at each terminal station

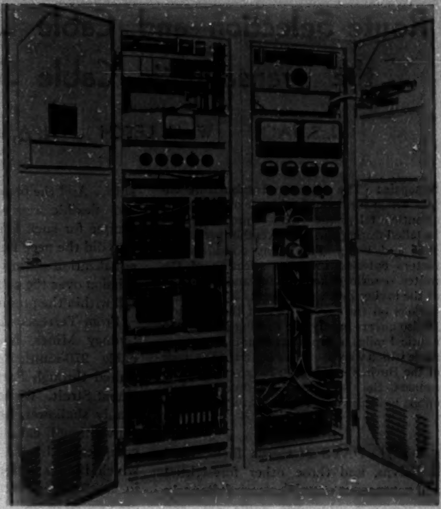

Fig. 7 (right). Power equipment

the laboratory and factory results that the regulation is better than ±1 ma for any alternating input voltage from 195 to 265 volts in the frequency range of 40 to 70 cycles for output voltages of 0 to 3 kv. The relatively long correction period of the magnetic-amplifier control circuit (about 0.5 second) is satisfactory with the type of no-break supply installed at the stations.

Another useful by-product of double-end feeding is that, when there is a shunt fault on the system, the voltages supplied from the two terminal stations give an indication of the fault position. Many factors will control the accuracy of the location, e.g., magnitude and position of the fault, and how nearly the currents fed from the two ends are equal. Calculations, confirmed by tests made with shunt faults introduced at Terrenceville, show that any continuous shunt fault that will affect transmission (to the extent of operating the 1-db pilot alarms) will be detected to an accuracy of ±1.0%. The limit is set by the accuracy with which the link voltage distribution can be measured.

Conclusions

The power-feeding system described is suitable for submerged-repeater schemes that can, in an emergency, be temporarily powered from one end only. For locations within reasonable reach of a central catastrophe-spare store the equipment should be sufficiently reliable not to need duplication at both terminal stations. For future schemes this will provide a method which is economically attractive compared with the present single-ended methods and which offers numerous electrical advantages.

The routine maintenance required on the power equipment could be further reduced if the few remaining electron tubes were replaced by electromagnetic components. On schemes where short interruptions to traffic do not involve a relatively high loss of revenue it would then be unnecessary for the local staff to maintain the high-voltage equipment, and the expensive no-break a-c supplies could be abandoned. The latter depends upon the probability of the primary sources at the terminal stations failing simultaneously.

Acknowledgments

The authors wish to express their thanks to many of their colleagues in the British Post Office and Standard Telephones and Cables, Ltd., who contributed to the developments described in the paper. The permission of the engineer-in-chief of the Post Office, and of Standard Telephones and Cables, Ltd., to make use of the information contained in the paper is also gratefully acknowledged. The equipments for the Clarenville–Sydney Mines link were manufactured by Standard Telephones and Cables, Ltd., at North Woolwich, London.

Route Selection and Cable Laying for the Transatlantic Cable System

J. S. JACK W. H. LEECH H. A. LEWIS

Synopsis: The repeatered submarine cables which form the backbone of the transatlantic telephone cable project were installed during the good-weather periods of 1955 and 1956. This paper considers the factors entering into the selection of the routes, describes the planning and execution of the laying task and presents a few observations on the human side of the venture. It also covers briefly the routing of some 55 nautical miles of repeatered submarine-type cable which were trenched in across the neck of the Burin Peninsula in Newfoundland to connect the Terrenceville submarine terminus with the cable station at Clarenville.

IN THE DAYS of Cyrus Field, Lord Kelvin, and those other foresighted and courageous entrepreneurs of the early transoceanic submarine cable era, the risks involved in selecting a route and laying such a cable must have appeared formidable beyond description. And indeed they were, for not until the third attempt was a cable successfully laid.

Today the hazards may be somewhat more predictable, our knowledge of the ocean bottom more refined, and our tools improved, but only to a degree. The task still remains extremely exacting in its demands for sound engineering judgment, careful preparation, high-grade seamanship, and good luck, weatherwise. For the basic methods now in use are still remarkably like those employed on the *Great Eastern* and other early cable ships, and the meteorological, geographical, and topographical problems have changed not at all.

In the current transatlantic project, the first transoceanic telephone cable system, there are two submarine links. Between Clarenville in Newfoundland, and Oban in Scotland there lie some 1,850 nautical miles* of North Atlantic water, most of it deep and all of it subject to weather of unpredictable and frequently unpleasant nature. The bridging of this required the laying of two 1-way cables over carefully selected routes, using an available cable ship. And the presence in these cables of 102 flexible repeaters posed problems unique for such long and deep cables, as also did the need for trimming the system equalization during laying so that transmission over the completed system would fall within the prescribed limits.

From Terrenceville, Newfoundland, to Sydney Mines, Nova Scotia, a single-cable 270-nautical-mile path was required through Fortune Bay and across Cabot Strait. While this water is considerably shallower, here again a relatively conventional cable-laying problem was complicated by the presence of repeaters which, in this section, were rigid units, 14 in number. (Two additional repeaters are located in the 55-nautical-mile section which is trenched in across Newfoundland from Clarenville to Terrenceville.) Trimming of system equalization was also required.

These cables were laid during the spring and summer months of 1955 and 1956. And the preparation for the laying required many months of effort in fields which were for the most part quite foreign to the usual scope of land wire telephone activity. Some appreciation of the problems encountered in this phase of the venture may be gained from the following sections.

North Atlantic Link

Route Selection

The first successful transatlantic telegraph cable was laid across the North Atlantic in 1866. Since that date 15 direct cables have been laid and five by way of the Azores. The approximate routes of these cables are shown in Fig. 1. It is at once evident that the shortest and possibly the best routes were already occupied so that selection of routes for the two transatlantic telephone cables could be expected to present some difficulty.

Some of the more important considerations which guided the selection were: 1. route length, 2. clearance for repairs, 3. trawler and anchor damage possibilities, and 4. terminal locations suitable for repeater stations, with staffing in mind, as well as facilities for onward routing, due consideration being given to the strategic aspects of the locations.

Route Length

Obviously, the shorter the length of a submarine route, the better. In the present instance, any system length much in excess of about 2,000 nautical miles would have resulted in a reduction in the number of voice channels which could be derived from the facility.

In Fig. 2 is shown a number of the routes to which consideration was given in the early planning stages. The distances shown are actual cable lengths and include an allowance for the slack necessary to assure conformance of the cable to the profile of the ocean bottom.

Route 1, from Eire to Newfoundland, at 1,770 miles, is the shortest route and in point of fact was provisionally suggested in 1930 for a new cable. But the difficulty of onward transmission of traffic to London made this route unattractive.

Route 2, from Newfoundland to Scotland, compared favorably in length with route 1, but its adoption was dependent upon location of a suitable landing site in Scotland.

Route 3, from Newfoundland to Cornwall, England, approximated 2,000 miles laid length and would have been very attractive had not so many existing cables terminated in southern Ireland or the southwest corner of Cornwall, which would lead to a great amount of congestion and consequent hazards to the telephone cables.

Route 4, from New York to Cornwall, was too long to be considered, as its length amounted to some 3,200 miles.

Routes 5, 6, 7, and 8 were indirect via the Azores. They were attractive, as only relatively short lengths were involved and suitable sites for intermediate cable stations could have been found on one of the several islands in the Azores. But difficulties attendant upon landing rights, and staffing problems in foreign territory were foreseen.

Clearance for Repairs

Repair of a faulty cable or repeater necessitates grappling, and in deep water this is likely to be a difficult operation. To avoid imperiling other cables while grappling for the telephone cables and, conversely, to provide assurance against accidental damage to the telephone cables from the grappling operations of others, it was considered essential that the route selected provide adequate clearance from existing cables. Suitable clearance is considered to be 15 to 20 miles in the

ocean, with less permissible in the shallower waters of the continental shelves.

TRAWLER AND ANCHOR DAMAGE POSSIBILITIES

It is probable that fishing trawlers cause more interruption of submarine cables than any other outside agency. Cables laid across good fishing grounds are always liable to damage from fouling by the otter boards of the trawlers. Final splices, either initial or as a result of repair operations, are especially vulnerable to damage because of the difficulty in avoiding slack bights at such points. It was desired therefore to avoid fishing grounds if at all possible.

If cables are laid in or near harbors frequented by merchant shipping, damage must be expected from vessels anchoring off shore in depths of less than 30 fathoms and proposed routes should therefore avoid such areas.

CABLE TERMINAL SITING

Location of the cable terminal stations must be considered from the standpoints of suitability of shore line for bringing the cables out of the water and also from the standpoint of amenities for the staff. This latter factor is most important in keeping a permanent well-trained staff. For example, owing to staff difficulties, it was necessary to move a terminal station of one company from the west side of Conception Bay in Newfoundland to a site within easy reach of St. Johns. A further factor in proper siting of the cable terminals is consideration for onward routing of the circuits carried by the cables.

And finally, in view of the importance, generally, of submarine cable facilities, it is considered desirable to avoid cable terminal locations in or near a potential military target area and, if possible, consideration should be given to underground protective construction for the terminal stations.

PRELIMINARY SELECTION

The routes for the telephone cables were considered in the light of the foregoing, and after preliminary discussion it was agreed that the two new cables should lie north of all existing cables, should avoid ships' anchorages, and should lie on the best bottom which could be picked, clear of all known trawling areas.

In 1930, American Telephone and Telegraph Company, in conjunction with the British Post Office, gave serious consideration to the laying of a single coaxial telephone cable between Newfoundland and Frenchport, Ireland (route 1, Fig. 2). A tentative route was plotted and the cable ship *Dominia* steamed over this, taking a series of soundings. These soundings indicated that good bottom was to be found about 20 miles north of the Hearts Content–Valencia no. 1 cable of 1873. This cable was the most northerly of the telegraph cables spanning the Atlantic. Study of its life history indicated that faults clear of the continental shelf were few and far between throughout its long life.

The latest British Admiralty charts and bathymetric charts of the U. S. Hydrographic Office for the North Atlantic Ocean were scrutinized and, from these and a study of all other relevant data, two routes were plotted which appeared to fulfill the necessary requirements so far as possible. However, it was agreed that if possible the selected routes should be surveyed so that minor adjustments could be made when desirable.

LANDING SITES

East End

It was now necessary to find suitable landing sites, with regard for the decision that the telephone cables should be routed north of all other existing cables.

On the British side it was necessary to look north of Ireland. The North Channel, the northern entrance to the Irish Sea, divides northern Ireland from Scotland and had this channel been suitable, the telephone cables might have been run

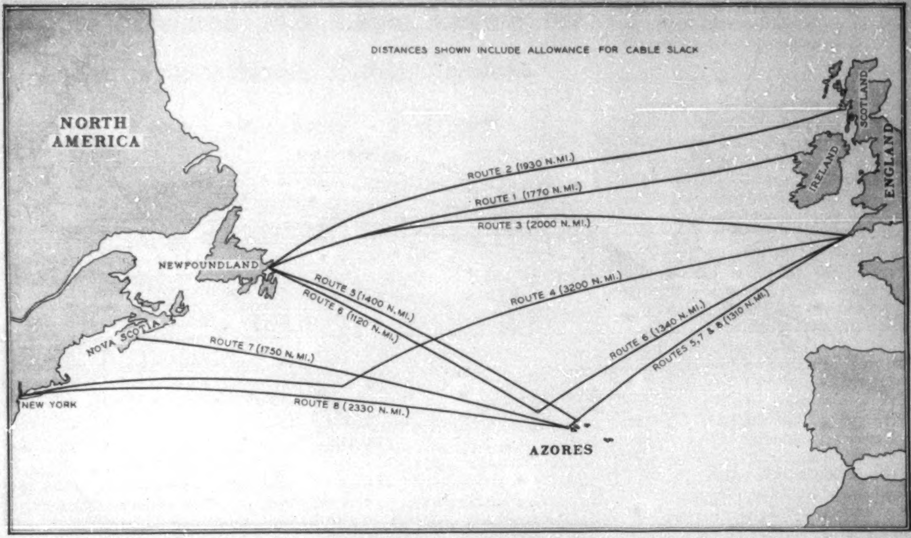

Fig. 2. Tentative telephone cable routes

through it to a terminal station on the southwest coast of Scotland in the vicinity of Cairn Ryan. However, the tidal streams through the channel are strong, at least 4 to 5 knots at spring tides; the bottom is rocky and uneven, with overfalls, and any cable laid through it would have a very short life indeed.

It was therefore necessary to search farther north. The west coast of Scotland presents a practically continuous series of deep indentations and bald, rocky cliffs and headlands. The chain of the Hebrides Islands stretches almost uninterruptedly parallel with and at short distances from the coast. It was obviously most desirable to land the cable on the Scottish mainland, and close to rail and road communication if possible.

From previous cable maintenance experience it was known that the Firth of Lorne which separates the island of Mull from the mainland was a quiet channel, little used by shipping or frequented by trawlers and with tidal streams which were not strong. Earlier passages of Post Office cable ships through the Firth had yielded a series of echo sounding surveys which indicated that, except for a distance of about 5 or 6 miles in the vicinity of the Isles of the Sea, the bottom was fairly regular. Several small bays on the mainland side of the Firth just south of Oban appeared from seaward to be very suitable landing sites and this was confirmed by a survey party, which selected a small bay locally named Port Lathaich for the cable landing and site of the station.

The fore shore was mainly firm sand with outcroppings of rock which could be avoided easily when landing the cables. The seaward approach was clear of danger and there was ample room to land two cables with a separation on the shore of some 30 yards.

Port Lathaich is only about 3 miles by road from Oban. Additional land cables would be necessary, however, to carry traffic to the main trunk network. From a strategic point of view, although Oban might possibly be considered a target area, the cable landing was sufficiently remote to be relatively safe, especially if the cable terminal station was sited in the rocky hillside. To ascertain whether any serious chafing or corrosion would result if cables were laid over the uneven bottom in the Firth, some 8 miles of coaxial cable with E-type armoring were laid over the area and recovered after 2 years. There was no evidence of any chafing or corrosion. It was therefore decided that the telephone cables should be routed through the Firth of Lorne to the cable terminal station site at Port Lathaich.

West End

The choice of a suitable cable landing in Newfoundland was more difficult to make, in view of the rugged and sparsely populated nature of the country. From Fig. 3 it will be seen that the existing telegraph cables spanning the Atlantic land either just north of St. Johns, in Conception Bay, or in Trinity Bay. North of Cape Bonavista the coast becomes more broken, and the sea approach is not good. Accordingly, there was no good alternative to routing both telephone cables into Trinity Bay, close to and northwest of the telegraph cable landing at Hearts Content on the southern shore of the bay. A survey party made an extensive examination of all likely places on the western side of the bay from Cape Bonavista in the north to Bull Arm at the southern end where, incidentally, the first successful telegraph cable was landed. Careful consideration of all of the places visited led to the agreement that Clarenville was the best site for a landing and for a cable terminal station.

Clarenville is at the head of the Northwest Arm of Random Sound. It is a junction on the main railway, and a good road to St. Johns will pass through the town in traversing its course from St. Johns to Port aux Basques. Clarenville has a growing population of some 1,600 inhabi-

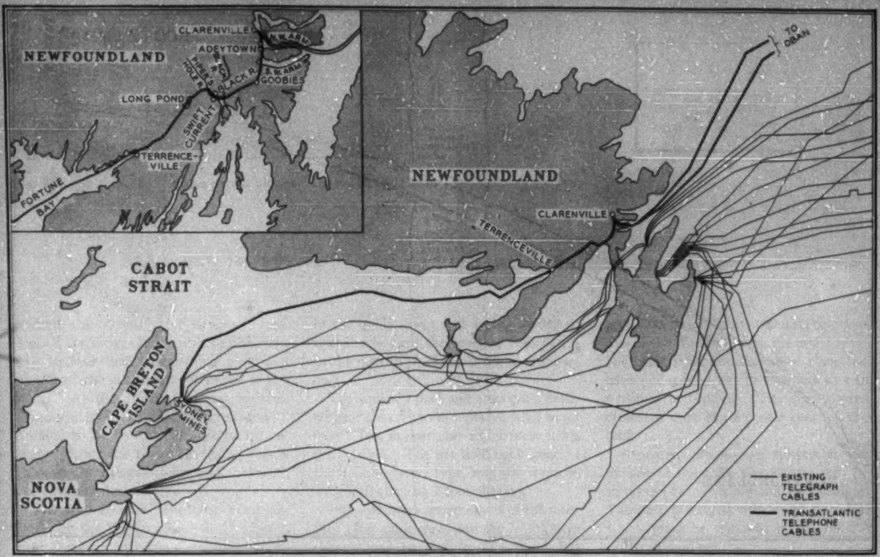

Fig. 3. Cable landings on Newfoundland, and final route of overland section of the Clarenville–Sydney Mines cable

tants, with stores and repair facilities of various sorts. Good cable landing sites are available just out of town and the approach from the sea up the Northwest Arm presents no navigational difficulties. Such few small vessels as ply to Clarenville during the summer months are not likely to interfere with the cables.

Final Route Agreement

Having agreed upon Clarenville, Newfoundland, and Oban (Port Lathaich), Scotland, for shore terminations, it was possible to complete the routes for the two cables as shown in Figs. 3 and 4. The final routes are clear of existing cables and they avoid crossing known trawling areas and anchorages. The cable stations are well sited with regard to staff amenities, accessibility, and strategic requirements. Soundings taken during the laying of the two cables showed a very even bottom except in the Firth of Lorne and one or two places in Trinity Bay. The general profile of the route is shown in Fig. 5.

It is considered that these routes have been selected with care and that they meet all the requirements of a well-planned cable project. Time alone will tell how well the objectives have been met.

Cable Laying

Early Methods

In 1865, when the legendary *Great Eastern* was pressed into service to lay the first successful transoceanic telegraph cable, she was fitted out with certain special cable-handling gear. The need for such gear had been amply demonstrated by events which transpired during two earlier and unsuccessful attempts by *HMS Agamemnon* and *USS Niagara*.

For her assignment, the *Great Eastern* was fitted with three large tanks into which her cargo of cable could be coiled. She was also provided with a large drum about which the cable could be wrapped in the course of its passage from the tanks to the sea. This drum was connected to an adjustable braking mechanism which provided the drag necessary to assure that the cable payout rate was correct with relation to the speed of the vessel. In addition, a dynamometer was provided so that the stress in the cable would be known at all times. A large sheave fitted to the stern of the ship provided the point of departure of the cable in its journey to the sea bottom.

On Friday, July 13, 1866, The *Great Eastern* steamed away from Valencia, Ireland, and 14 days later, on July 27, she arrived off Trinity Bay, Newfoundland, and completed the landing of the western shore end.

HMTS Monarch

Early in the planning for the transatlantic project it was realized that in no small measure the success of the venture would depend on availability of a vessel suitable for laying the cables. It was extremely fortunate that one of the partners to the enterprise was also the owner and operator of the largest cable ship in all the world, and one well suited to the task at hand.

The twin-screw cable ship *Monarch*, Fig. 6, was built for H. M. Post Master General by Messrs. Swan, Hunter, and Wigham Richardson, Ltd., at their Neptune Works, Walker-on-Tyne. She was completed in 1946. This ship is of the shelter deck type, having principal dimensions as follows:

Length over-all.......	482 feet 9 inches
Breadth molded......	55 feet 6 inches
Depth molded to shelter deck...........	40 feet 0 inches
Gross tonnage........	8,056

The ship has an overhanging bow which carries three cable sheaves, a cruiser

stern with the after paying-out cable sheave offset on the port quarter, a semibalanced rudder having extra large surface, and a cellular double bottom extending from the collision to the aft peak bulkheads. Both main and shelter decks are steel and they extend her complete length.

The cable is carried in four welded steel cable tanks fixed to the tank top plating. These are arranged along the ship's center line in a fore-and-aft direction forward of the main propelling machinery space. They are each 41 feet in diameter and have the following cubic capacities:

Tank, No.	Coiling Space	Gross Cubic Feet
1	33,730	40,170
2	31,820	38,460
3	30,865	37,375
4	30,230	36,300

The opening in the shelter deck above each tank is a circular hatch 8 feet in diameter.

A watertight cone of steel plates is built in the center of each tank to ensure against fouling of the cable during payout. Further control of the cable is provided by a crinoline, Fig. 7, which is a circular spider of steel tubing normally suspended from 1 foot to 3 feet above the top layer of cable in the tank. The crinoline tends to prevent flying bights of cable and also provides a safety platform, in case of trouble for the men who work in the cable tanks. Each crinoline may be raised and lowered by an electric motor drive.

The maximum cable-carrying capacity is approximately 5,000 long tons, or almost 2,000 miles of the deep-sea type of cable used on this project if no repeaters were involved.

The *Monarch* is driven by two steam engines. The maximum propeller revolutions are estimated at 110 per minute, giving a ship's speed of about 14 knots.

Two cable engines are fitted forward, both capable of being used for picking up or paying out. These are driven by electric motors having a maximum rating of 160 horsepower which will permit picking up at a rate of 0.9 nautical mile per hour with a stress of 20 tons, or at 3.5 knots with a stress of 5.3 tons. The drive system is constant current, so designed that a uniform torque may be held at the drum for any setting of the speed control. When paying out, these motors operate as generators to provide electrical braking, and auxiliary mechanical brakes are also provided.

A single cable engine is fitted aft and this is the main paying out gear. In addition to the electric brake, the aft engine is provided with a multiple drum externally contracting band brake, manually adjustable and water-cooled, and with a further auxiliary fan brake. The fan shaft is driven in such a manner that when cable is being paid out at approximately $8^3/_4$ knots, the fan will revolve at 1,000 rpm and absorb 120 brake horsepower. Adjustments in this are effected by varying the amount of opening in the fan shroud so that as little as 27 brake horsepower may be absorbed.

Dynamometers, both fore and aft, provide for measurement of the cable tension. Taut-wire gear is furnished on the starboard quarter to provide an effective means for calculating the amount of slack paid out. With this gear, steel piano wire, anchored to the bottom, is paid out at constant tension and provides a rough measure of distance steamed over the ground. A test room with trunks to each cable tank is provided on the shelter deck and fitted with instruments for measuring and locating faults.

Modifications for Flexible Repeaters

In the normal cable-paying-out process, the cable is drawn from the tank, carried along fairleads to the holdback gear (a mechanism for applying slight tension to the cable so that it will snub tightly

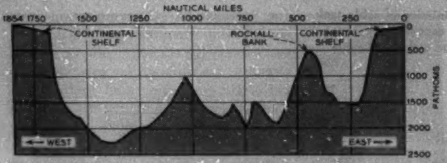

Fig. 5 (above). Profile of ocean depths between Clarenville and Oban

Fig. 6 (right). HMTS Monarch

around the drum), and then wrapped around the drum of the cable engine from two to four turns, depending upon the weight of the cable and the depth of the water. At the drum, a fleeting knife is fitted which pushes over the turns already present to make way for the oncoming turn. From the drum the cable passes through the dynamometer and thence to the overboarding sheave.

The Bell System repeaters, manufactured by the Western Electric Company, were designed with the objective of making them act as much like cable as possible.[1] Despite this, their presence introduced a loading and laying problem as their ability to bend without injury is limited to about a $3\frac{1}{2}$-foot radius, and their structure is such that unnecessary bending may present a hazard to their watertightness. As the majority of the sheaves and drums of the conventional laying gear are considerably smaller than 7 feet in diameter, a number of modifications were required in the *Monarch's* equipment to satisfy the repeaters.

For the most part, the new gear was designed by the Telegraph Construction and Maintenance Company, Ltd., to broad requirements supplied by the American Telephone and Telegraph Company. The modifications included providing the port bow sheave with a flat tread to bring its diameter to 6 feet 10 inches, and replacing both forward dynamometers and the aft dynamometer by a new design employing a 7-foot wheel in a pivoted A-frame bearing on Elliott pressure-type load cells. In this arrangement port and starboard forward drums were replaced with drums of maximum possible diameter without a major change in the complete gear. This diameter proved to be 6 feet 10 inches on the tread. The after paying out drum was replaced with one having a 7-foot diameter. The forward port and aft cable drums were equipped with ironing boards. (An ironing board is a curved shoe placed adjacent to the cable drum and spring loaded so that it will force the repeater to conform to the curvature of the drum as it passes on.)

The forward port and starboard draw-off gear sheaves were replaced with larger ones 7 feet in diameter which were made traversable. The aft hold-back gear, of the double-sheave type, was also replaced with units having 7-foot sheaves.

Fig. 8 shows a general view of the modified after cable gear, and the 7-foot stern sheave may be seen in Fig. 9. A line schematic of the gear is shown in Fig. 10.

Roller-type fairleads shaped into arcs of minimum $3\frac{1}{2}$-foot radius were fitted at each cable tank hatch, with smaller roller guides at convenient points to assure fair lead of the cable from the tanks to the cable machinery. Electric hoisting gear was provided for the lower crinoline in each tank as it was necessary to raise the crinoline whenever a repeater left the tank.

The test room was greatly enlarged and fitted with the special gear necessary for powering and measuring the system during laying.

LOADING CONSIDERATIONS

When the ship is loaded, the cable is coiled carefully in the tanks, layer upon layer, each layer being called a "flake." The coiling is started from the outside of the tank and progresses clockwise toward the center so that the armor is untwisted one revolution for each complete turn in the tank. When paid out in the reverse order, this twist is restored.

Handling of the repeaters during loading presents a problem because of the need to restrict their bending. After some experimental work, splints were devised to provide the needed rigidity. These consisted of two angle irons each 12 feet long and equipped at the ends with cold-rolled steel rods ranging in length from $1\frac{1}{2}$ to 6 feet. By this device it was possible to maintain rigidity over the main central portion of the repeater, including the junction of the core tube with the end nosing, and provide limited flexibility along the outer ends of the core tubes which are less sensitive to bending. The splints were removed, once the repeater reached the tank.

Repeaters are always stowed at the outside of the flake where they need be subjected to only a minimum of bending. They are protected with wood dunnage, which must be removed before the repeater is paid out.

With these modifications all repeaters and equalizers were laid successfully from either forward or aft gear at a cable speed of around 3 knots.

TESTING AND EQUALIZATION

Purpose

Once a submarine cable system has been installed, it is accessible only at the ends for adjustment to improve performance, save at great difficulty and large cost. As some irregularities cannot be corrected from the ends, it behooves the designers to discover and account for such irregularities and to correct them before the cable is finally on the ocean bed.

The laying period offers the last opportunity for accomplishing this and, indeed, all too frequently, also the first. This fact, coupled with the broadband design of the link and the presence in the system of active elements (the repeaters), necessitated a very comprehensive program of tests and measurements during laying.

The program had three specific purposes: 1. to detect immediately any fault which might develop during laying, 2. to permit the design and execution of corrective system adjustments while en route so that transmission performance of the completed link would fall within specified objectives, and 3. to gather data on system characteristics at intermediate points for eventual use in fault location or

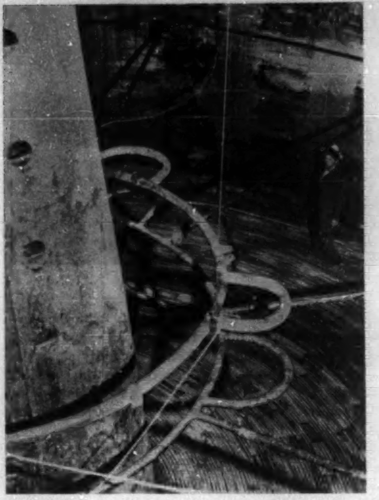

Fig. 7. Interior of cable tank showing central cone, crinoline, and a flake of cable

in aging studies. The need for parts 1 and 3 of the program is more or less self evident, but part 2 merits some further discussion.

In an ideal submarine cable system in an average environment, the attenuation of the cable from one repeater to the next would be offset exactly across the frequency band by the gain of the following repeater. Such a result is never achieved in practice, as the temperature and pressure environments (which affect cable attenuation) cannot be known precisely in advance, and the cable structure itself cannot be manufactured for mile after mile without variation in transmission characteristic. Additionally, the mechanics of the laying process induce minor changes in the physical structure of the cable which are reflected in attenuation changes.

If such deviations from desired characteristic produced only differences from the specified system gain objective, compensation could be readily applied at the ends of the submarine link. Unfortunately, this is only partly the case. Their more important effect is the resulting misalignment of operating levels of individual repeaters from design objective.

Misalignment magnitudes must be watched carefully for, at best, misalignment narrows the system latitude for seasonal temperature changes and for aging, and at worst it can result in intolerable system noise. If a repeater is preceded by too much cable the signal-to-noise ratio at the repeater input will be less than desired because of thermal noise. In the opposite case of too little cable, the signal level will be too high and the resulting overloading in the repeater will also affect the signal/noise adversely. Once present on the signal, the noise cannot be removed, and so the cure for excessive misalignment must be applied before the misalignment has developed. Adjustments at intermediate points along the route must therefore be contemplated.

Testing Program

The program which was evolved to meet the three objectives outlined was meticulously reviewed and practiced before the start of laying, and various forms were prepared for entering data and plotting and evaluating results. This was essential to avoid wasting effort or missing valuable data. The wisdom of this was fully apparent to all involved after experience with the close time schedules and the mental tensions which developed during the actual laying.

Staffing for testing was provided by crews of two or three trained engineers located at the transmitting cable station and on shipboard. Those on the ship served $4^1/_2$-hour watches at 9-hour intervals, which permitted a reasonable amount of rest, and avoided continuous "dog watch" duty by any one crew.

Close contact between shipboard and cable station crews was essential, and was achieved by cable and radio order circuits (or "speakers"). Communication from shore to ship when the cable was powered made use of the standard cable order wire circuit at the cable station to apply a signal in the frequency band 16 to 20 kc. The signal was demodulated and amplified aboard ship by a special stripped version of this same gear. The radio order circuits employed special land antennae and equipment and, for the most part, the ship's standard single-sideband telephone set, although other equipment at medium frequency was sometimes used for short distances. Radio telegraph with hand keying was available for backup when conditions were too poor for the radiophone sets.

Plans called for powering the cable at all times except when splices were being made. This was necessary, of course, for the measurement program, but it also provided additional assurance of the safe laying of repeaters, as the glassware and tungsten heaters of the electron tubes are more resistant to damage when hot. Power for the first half of each crossing was provided from the cable station. Beyond this point, the required voltage would have become excessive and so the shipboard supply was inserted into the series power loop and its voltage adjusted in proportion to the amount of second-half cable actually in the loop.

Monitoring against the possibility of faults was accomplished by measurement of a pilot tone at 160 kc, transmitted over the cable at all times except when data were being taken or power was turned down. Audibly alarmed limits were set on the measurement to indicate any significant deviation in transmission. In actuality, all unanticipated alarms received were found to have resulted from frequency or voltage shifts in the primary shipboard supply for the measuring equipment.

During the design of the system,[2] consideration of the misalignment problem had indicated the desirability of splitting the cable for each crossing into a number of sections, called "ocean blocks." These contained either four or five repeaters, and were 150 to 200 miles in length. In loading the ship, the two ends of each ocean block were left accessible for connection to the test room and for splicing operations.

Measurements made in the spring of 1955 off Gibraltar had indicated an unexpected change in attenuation called "laying effect,"[3] which required some last-minute adjustment of the repeater section lengths. With incorporation of these changes, it was known that the factory lengths of cable between repeaters

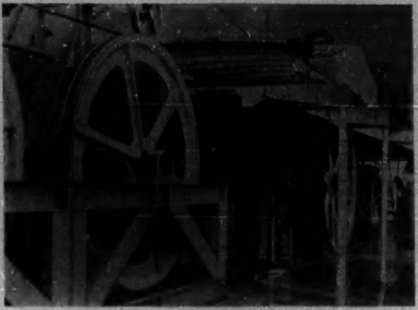

Fig. 8. General view of modified after cable gear (one of two hold-back sheaves, drum with fleeting knife and ironing board and, at extreme right, dynamometer sheave)

Fig. 9. Cable payout over the stern

were adequate to keep misalignment within an ocean block within reasonable limits. The system could then be equalized between ocean blocks so that the signal level at the first repeater of a new block would be approximately correct, and the total system noise thus would fall within limits.

This equalization was accomplished in two ways. Excess cable of the order of 1/2 mile to 3 miles in length was provided at the top end (first end out of the cable tank) of each ocean block. Based on measurements, this could be cut longer or shorter than the nominal spacing of repeaters, so that the repeater gains and cable losses would be matched at some frequency in the band. Residual deviations in other parts of the band could then be mopped up if necessary by inserting a simple equalizer, housed in a container similar to those used for the repeaters. Ten such equalization points were provided in each cable.

In practice, sending levels were adjusted at the cable station to give test tones at the grids of the output tubes of the repeaters which, if the system equalization were perfect, would be flat across the frequency band, and at the proper level. These tones were measured on shipboard at the end of the ocean block being paid out. The results were plotted against mileage, with one sheet for each frequency being measured. Because of the laying effect and of temperature and pressure changes on the cable as it progressed to the bottom, these plots displayed a slope.

The value of loss (or gain) to be ascertained for each frequency was that which would exist when the entire ocean block was on the bottom. To obtain this, it was necessary to extrapolate the curves to the mileage point representing the end of the block in question. The extrapolation was required to avoid stopping the ship at the end of the block, and so had to anticipate the time needed for turning over and cutting the cable end at the proper point, and making one or two splices (depending on whether or not an equalizer was inserted at the point in question).

Having read the extrapolated values from the curves, these were compared with objectives for the particular block junction, and the deviations plotted. Transparent overlays, showing the net effect of each of several types of equalizer combined with varying amounts of cable around the nominal spacing, greatly facilitated the final decision as to cutting point and equalizer choice. This implementation of the system's undersea equalization represented a very large part of the effort required of the testing crews during laying.

Additional data gathered for fault location, aging studies, and for other purposes included precise determination of repeater crystal fequencies[2] on the bottom, gain frequency runs to show up any fine-grained structure which might exist in the band, and values of the current and driving voltage.

Copper resistance and capacitance measurements proved of dubious value; in the first case because of the temperature-resistance characteristic of the electron tube heaters; in the case of capacitance, probably because of polarization effects in the castor oil capacitors used in the repeaters.

Shipboard Test Equipment

A new test room had been equipped for making these measurements with transmitting and receiving transmission measuring sets,[3] including the crystal test panels. These sets were provided in duplicate to forestall difficulty should one set develop trouble during the laying. The transmitting consoles were required only for use in calibrating the receiving sets, and for some measurements which were made on individual ocean blocks in the ship's tanks.

Additional gear in the test room included a cable current power supply,[4] and a "Lookator," which is a pulse echo type of fault locator useful from a point in the cable to the adjacent repeater on either side.

LAYING SEQUENCE

HMTS Monarch is the largest cable ship afloat, with capacity for about 2,000 miles of the type-*D* deep-sea cable in her tanks. However, because of the inherent limitation on their bending radius, the presence of flexible repeaters in the cable puts a restriction on the height to which the coil can be permitted to rise in the tanks. Therefore, for repeatered type-*D* cable, the *Monarch's* capacity is cut back to about 1,600 nautical miles.

Types *A* and *B* cable, used in shallower water, are considerably larger and heavier than type-*D* and, consequently, less of these can be carried.

The ideal laying program would have involved one continuous passage across the North Atlantic from cable station to cable station. However, this would have required carrying over 1,900 miles of ca-

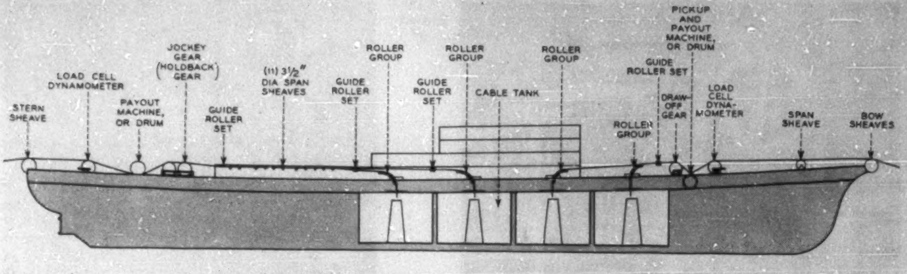

Fig. 10. Line schematic of after-cable gear on Monarch

ble, including about 300 miles of type *A* and something less than 50 miles of type *B*. Such an amount of cable would greatly exceed the ship's capacity.

Each cable was therefore laid in three sections. The no. 1 cable (southernmost), which transmits from west to east, was laid in the following sequence: Clarenville to the mouth of Trinity Bay, a distance of 200 miles; thence about 1,250 miles to Rockall Bank (a submerged plateau); and finally the remaining 500 miles from Rockall Bank to Oban. The no. 2 cable followed the opposite sequence, starting at Oban and proceeding in three sections of 500 miles, 1,250 miles, and 200 miles to the terminal at Clarenville. Shore ends, about 1/2 mile long at Clarenville and 2 miles at Oban, were prepared and put in place in advance of the time when they would be needed. At each intermediate point, the cable was "buoyed off" with a mushroom anchor, connecting lines, and a surface buoy of size appropriate for the water depth.

The mileages indicated are actual cable lengths. They exceed the geographical distances between the points involved because of the slack allowance which experience has shown to be necessary to assure reasonable conformance of the cable with the contour of the ocean bed. Normally, about 5-per-cent slack is considered desirable in deep water, with the allowance decreasing in steps to zero in shallow water.

All available information indicated that the most favorable weather conditions in the North Atlantic could be anticipated in the period of May through August. Before May, ice could be expected along the western sections of the route and after August, hurricanes were likely, and later the winter storms.

Laying of the no. 1 cable was started June 28, 1955, and completed September 26. The actual laying period took but 24 days in this interval, the remainder of the time being spent in transit and in reloading. The no. 2 cable was started June 4, 1956, and completed August 14. About 16 laying days were involved.

The routine aboard ship during laying consisted in passing out cable at the rate of 6 to 7 knots for a repeater section length of a little over 37 nautical miles, then slowing down to about 3 knots as the repeater passed through the cable machinery and overboard, then renewing speed again. During all of this period, the testing crews, both on shipboard and at the transmitting cable station, were busy measuring, recording data, and planning the equalization trimming. At a point shortly after the passage of the next-to-last repeater in an ocean block, special measures were required for the equalization program. From that point until the joints associated with the connection to the following ocean block had been completed, the speed was reduced to 5 knots. The need for this arose from the following considerations.

Stopping of the ship in deep water introduces serious possibility of formation of kinks in the cable, and is to be avoided at all costs. To permit continuous laying, it was necessary to determine the amount of cable needed for equalization, to measure out this cable, and to complete the splices before reaching the end of the block being laid.

The addition of an equalizer at the end of the block requires two joints and armor splices. Preparing the cable ends, brazing together the center conductor and associated tapes, injection-molding the polyethylene around the center conductor, replacing and overlaying the armor wires, and binding the splice, consumes 6 to 7 hours for a single splice, and 8 to 9 hours for two splices when overlapping of operations is practical. An allowance of 3 hours is considered necessary for remolding in event of a defective joint (disclosed by X-ray inspection). The time allowance required to complete the splicing of ocean blocks is therefore 9 to 12 hours. About $1^{1}/_{2}$ hours are needed to carry out the extrapolation, make the equalization decision and turn over cable to the cutting point. During the interval between the cable cut and the completion of the joint, the ship's speed was maintained at 5 knots so as to minimize the distance over which extrapolation of equalization data had to be extended. Even so, the final extrapolation covered the last 60 miles to 75 miles of each ocean block.

During the jointing intervals, system power was turned down to avoid any hazard to the members of the jointing crew. It was restored as soon as the moldings had been X-rayed and the outer or return tapes had been brazed. These activities were so timed that in almost every case the system was powered as each repeater went overboard.

Clarenville–Sydney Mines Link

Route Selection

Clarenville having been selected as the site of the cable terminal station on the west end of the ocean crossing, it was necessary to consider how the system was to be extended to Nova Scotia for connection with the North American continental network.

A number of alternatives were possible, as described in the following.

Alternative 1 contemplated radio relay across Newfoundland to Port aux Basques, and thence across the Cabot Strait. However, a survey revealed that maintenance access to suitable sites would be most difficult, particularly in winter, and primary power was not obtainable.

Alternative 2 involved a poor submarine route around the Avalon Peninsula to possibly Halifax, Nova Scotia. The length of the sea cable would be about 600 nautical miles. It would be necessary to cross many working telegraph cables (see Fig. 3). Trawler damage could be expected as the cable would need to traverse known trawling areas, and during the winter months any repairs would be costly and prolonged. Also, it was not desired to lay another cable out of Trinity Bay as the route might be wanted for a second transoceanic cable at some future time.

Alternative 3 involved a submarine cable from Clarenville out through the North West Arm to Rantem at the head of Trinity Bay, a short land cable across the isthmus, and thence either a submarine cable direct to Sydney, Nova Scotia, or a land crossing of the Burin Peninsula at Garnish and thence by submarine cable to Sydney. This route involved three open-sea sections with one or two land sections. There was rather limited space for a cable in Placentia Bay and the bottom was uneven and rocky. Existing cables laid around the Burin Peninsula have had interruptions which indicated an unsuitable bottom, and fishing trawlers had been seen in the vicinity recently.

Alternative 4 also involved a cable overland, from Clarenville to Terrenceville at the head of Fortune Bay, there to join a direct submarine cable to Sydney Mines. Three short underwater sections would be involved in the Clarenville-Terrenceville link, but these could be in shallow water, out of harm's way. The main submarine route from Terrenceville to Sydney Mines would be clear of other cables and would avoid trawling areas and anchorages, a not inconsiderable achievement in view of the congestion of submarine cables and the fishing activity around the southeast corner of Newfoundland. Further, a good landing site in Nova Scotia was available near Sydney Mines on property owned by Eastern Telephone and Telegraph Company.

After due consideration, alternative 4 was chosen as being the most satisfactory from all aspects, and the final route is shown in Fig. 3. This route is considered to be most likely to have a good life history. While it would have been possible to have one continuous land cable between Clarenville and Terrenceville, the three short underwater sections saved a considerable amount of trenching without adding undue hazard to the system.

CLARENVILLE-TERRENCEVILLE ROUTE

Routing the Post Office single-cable system overland from Clarenville to Terrenceville having been decided upon, a number of other matters required decision. The first was the type of cable to be employed for this section. Several alternatives were considered, bearing in mind factors such as the type of terrain, access, availability of primary power, possible future expansion of capacity and, of course, interference from static and radio frequency pickup. The advantages of using standard solid dielectric coaxial ocean cable with submarine-type repeaters were judged to outweigh all other considerations, and left only the problem of shielding from interference.

Up to this time, shore ends of submarine cables used by the Post Office were shielded for about a quarter of a mile from shore by a lead sheath insulated from the return tapes of the coaxial by a polyethylene barrier. Experience indicated that such shielding might not be adequate over a long distance on land. The question was resolved by the addition of iron shielding tapes and a plastic jacket to standard submarine cable. The structure is described elsewhere.[5]

Through the use of this robust, wire-armored cable and two steel-housed submarine repeaters, no limitations from the noise pickup angle were placed on the detailed route selection for the overland section. The first thought was to try to proceed directly across country from Clarenville to Pipers Hole River, saving at least 10 miles over a route which followed the road, and on which advantage might be taken of quite long water stretches into which the cable could be dropped. Black River Pond, for instance, is $4^1/_2$ miles long. This proposal was abandoned after surveys, because of the very rocky nature of the country and the difficulty of access both for construction and any subsequent maintenance, and it was decided to follow the general course of the roads.

It was possible to avoid trenching in the rocky, precipitous cliff country from Clarenville to Adeytown by laying about 6 miles of cable in the water of Northwest Arm. Similar considerations dictated the choice of 2 miles of cable in the sea across Southwest Arm. Thence the route followed the road, at a distance ranging from 250 yards to more than a mile, as far as Placentia Bay, taking advantage of the larger ponds, where possible, to avoid trenching.

Reaching the 800-foot-high ground beyond the Pipers Hole River from the north of Black River proved quite difficult. Here the road is carved out of the foot of the cliffs as far as Swift Current and the country behind is solid rock. Plans exist for a hydroelectric project involving dams in Pipers Hole River just north of the road crossing and it naturally would not be desirable to bury a cable in such a locality. The river estuary itself passing by Swift Current presents only a narrow 6-foot deep navigable channel at low water but it was decided that this could be used for some 6 miles by employing a barge and a shallow draft tug for the laying.

To locate a suitable route out of the basin up through wooded gorges to the top took about a week of very rough work. Thereafter, all was "plain sailing;" advantage was taken of ponds such as Long Pond (4 miles) and Sock Pond (3 miles) until the route arrived within 6 miles of Terrenceville.

Here it was reluctantly decided to bury the cable in a deep trench on the inner side of the road, as the other side falls sharply to the sea. The desire to avoid roads was due to their instability and the methods used for construction and repair. This road is dirt only, with no foundations, and in this particular area, sections have been known to slide away into the river bed below. The final length of cable laid was just short of 55 nautical miles.

CABOT STRAIT LAYING

Coaxial submarine cables in which rigid repeaters are inserted cannot be laid with the existing cable-laying machinery except by stopping the ship, removing the turns of cable from the drum, and then passing the repeater by the drum and restoring the turns. Special equipment is also needed for launching the repeater over the bow sheaves.

SHIP MODIFICATIONS

The following equipment was installed on the *Monarch* for the laying of cables carrying rigid repeaters: A gantry over the bow baulks, consisting of a 22-foot steel beam projecting 6 feet beyond the sheaves, was installed for handling repeaters at the bow. This gantry was fitted with an electrically operated traveling hoist for lifting the repeaters over the bow sheaves and lowering them into the sea. A stand-by hand-operated lifting block and traveller were provided to guard against failure of the power point.

A rubber-tired, steerable steel dolly (or trolley) was developed from the chassis of a small car to transport the repeaters from the cable tank hatches to the bow sheaves. These repeaters weigh about 1,200 pounds.

Storage racks were built up from steel sections provided with shaped, rubber-lined wood blocks and were fitted at each cable tank hatch on the shelter deck. Each rack held four repeaters in double tiers. A hand-operated lift was furnished for moving the repeaters from the storage racks to the dolly.

A special quick-release grip was furnished for use when lifting the repeaters by the electric hoist on the bow gantry. Deflection plates were also fitted on the fore deck around dynamometers and hatches to avoid their fouling the dolly.

LAUNCHING RIGID REPEATERS

The rigid repeaters were stowed in their racks in the order of their laying. The bights of the cable attached to the ends of the repeaters were brought up the sides of the cable tanks, secured along the arms of the crinoline and up the sides of the hatch coamings to the deck, clear of the running length of cable and from where the repeater could be drawn forward along the deck on the dolly.

When the time came for a repeater to be laid, speed was reduced and the ship finally stopped head to wind. A 6-by-3 compound rope from the starboard cable drum was secured to the cable just abaft the bow baulks. Sufficient cable was then paid out until the tension was taken up by this rope. The turns of the running cable were then removed from the port cable drum and the resulting slack cable worked overboard by paying out the starboard drum rope which was holding the tension. When the excess cable had been cleared from the deck, the repeater on its dolly was carefully hauled along the fore deck to the traveling hoist of the overhead gantry. Cable was then drawn from the tank so that the turns could be re-formed on deck and replaced on the port cable drum. The repeater was lifted from the trolley and traversed outboard as soon as it was high enough to clear the bow baulks. It was then lowered to the water's edge and when the tension had again been taken by the cable, the quick release grip was slipped and the starboard drum rope cut. Paying out was then resumed.

LAYING PROGRAM

On February 1, 1956, the *Monarch*, having returned to Ocean Works, Erith, after refitting, commenced loading the various sections of cable to be used for the Terrenceville–Sydney Mines route. The sections were all carefully tested and measured in the Works before loading. The cable ends were clearly marked and dogged together by a length of rope which was not removed until the repeater had been jointed into its connecting sections of cable.

Loading of the cable and splicing in of repeaters was finished by April 10 and the system tested and checked. The *Monarch* sailed for Sydney Mines on April 18 and arrived there April 30. The cable station is situated about $1^1/_2$ miles inland from the shore, with a small lake intervening. A length of type-*B*, insulated-outer-conductor, lead-covered cable had previously been laid from the station across the lake to a narrow strip of land which separates it from the sea. The joint to the main cable was to be made on this strip. Two medium-sized shore-based motor boats were used to tow the end of the double-armored section of cable from the *Monarch* to the shore. During this journey the cable was supported by empty oil drums at close intervals. When the motor boats had reached shoal water, the end of the cable was secured to a landing line and two tractors took over the hauling.

When enough cable was on shore to make the joint and the splice, the barrels were cut away and the *Monarch* weighed anchor and paid out this section of double-armored cable on the agreed route and buoyed off the end. She then steamed over the proposed track to Terrenceville, taking soundings and sea bottom temperatures as required, and anchoring off Terrenceville on May 3.

Preparations for landing the end were at once put in hand and the ship's motor launches towed the end of the cable towards the cable landing, the cable again being supported by empty oil drums. This end was jointed and spliced to a piece of cable which had been laid previously from the Terrenceville cable hut to a sand split which juts across the head of Fortune Bay, about a mile away.

Upon completion of the splice, over-all tests were made from the ship to the Terrenceville cable hut and, all being well, paying out toward the buoyed end off Sydney Mines was begun on May 4. The first repeater went over about 2 hours after the start of laying and the others followed at approximately $4^3/_4$-hour intervals.

On May 7 the cable buoy on the Sydney Mines end was recovered and the end hove inward. After tests in both directions, the final joint and splice were made. This operation was completed on May 9 and on receipt of a signal that all was well the *Monarch* proceeded into harbor at Sydney to land testing equipment, a spare equalizer, and other equipment.

EQUALIZATION AND TESTING

The cable had been loaded into the ship in repeater section lengths, so cut that when laid at estimated mean annual sea temperature, the expected attenuation would be 60 decibels at 552 kc. A correction for the change in attenuation of the cable when coiled in the factory tanks and when laid in about 100 fathoms had been determined from tests on two 10-mile lengths of cable, laid off the Island of Skye. The correction amounted to a decrease in attenuation, when the cable was laid, of 1.42 per cent. This was essentially an empirical result, and as the mechanism of the change was not fully understood, a possible further inaccuracy of equalization might arise.

Sea-bottom temperatures along the route were obtained from information supplied by the Fisheries Research Board of Canada but, unfortunately, this information was rather meager and varied considerably with locality.

Since the cable equalization built into the repeater differed appreciably from the final determination on laid cable, it was found necessary at a comparatively late stage to introduce an undersea equalizer into the center of the sea section. This was intended to eliminate a flat peak of loss of 3.5 decibels, expected at about 100 kc. So that the last repeater should not lie too near the beach at Sydney Mines, a network simulating 9 miles of cable was also inserted in the undersea equalizer.

The repeaters were spliced into the cable lengths on board the *Monarch* and tests were made at every stage of the build-up of the system. The equalizer was permanently jointed to the first half section of seven repeaters and left with an excess length of tail which could be cut as desired during the laying operation to further improve the equalization. The first and second halves of the system were temporarily connected through power separation filters so that the whole system could be energized just prior to laying.

The test routine included attenuation measurement at five frequencies in each direction, of transmission, noise, pulse and loop-gain, supervisory measurements, d-c and insulation resistance, and capacitance. The *Monarch* test room therefore contained two sets of terminal equipments similar to those installed at Clarenville and at Sydney Mines.

It was decided to energize the system continuously during the laying except for the few hours when power had to be removed to make the equalizer splice. This enabled a continuous-order (speaker) circuit to be operated over the cable, and minimized the number of energizing and warm-up periods. The only disadvantage, considered to be slight, was the necessary omission of insulation resistance and capacitance measurements during laying, except in the course of the equalizer-splicing operation.

The plan was to lay from Terrenceville in the direction of the high-frequency band and to test the system to the *Monarch* during the laying from this shore station. The overland section between Clarenville and Terrenceville, which contained two repeaters, was connected on with appropriate equalization after the submarine section had been satisfactorily completed and tested.

At Terrenceville, after the cable end had been taken ashore and the beach joint completed, the system was energized from the *Monarch* with a d-c power ground at Terrenceville for the necessary 4-hour minimum warming-up period. The first set of routine measurements of the laying operation was then carried out. Thereafter, a complete set of measurements on the Terrenceville half of the system was made after every 10 miles of cable laid. An occasional check set of measurements was also made on the Sydney Mines half of the system in the tanks.

The primary object of these tests was to determine what length of cable should be inserted between the equalizer and the eighth undersea repeater to obtain the optimum system. In practice this resulted in arranging for a length of cable so that the output level of the eighth repeater at 522 kc should be equal to that at the output of the first repeater at the assumed mean annual temperature of 35.1 degrees Fahrenheit.

The estimated length of cable required for this purpose was plotted after each measurement. It became evident soon after laying the fifth repeater (94.6 nautical miles of cable laid) that the linear relation obtained could be extrapolated with adequate accuracy to specify safely a length of 6.06 nautical miles of cable between the equalizer and the adjacent repeater.

This decision on length was taken and, after removing power, the equalizer was accordingly jointed in, the operation being completed before it was necessary to pay out the splice. During this period, capacitance and conductor and insulation resistances were checked on each half. During the laying of the second half, measurements were made as for the first half. On arrival at the buoyed shore end, a final complete set of measurements was made and these, suitably corrected for the shore and length, were transmitted to Sydney Mines so that the first measurements from Sydney Mines to Clarenville could be checked with those obtained on the ship.

Sidelights

Weather

Weather is the undetermined element in cable-laying and repair activities. With few exceptions the transatlantic project was blessed with remarkably good weather. The exceptions were, however, noteworthy.

Heavy snow squalls were encountered off Terrenceville during the operations in the vicinity. At Rockall Bank on the first lay one heavy storm came up as the last repeater in the 1,250-mile section was going over, and made this launching and the subsequent buoying of the end very difficult operations. Both were accomplished successfully as a result of the superb seamanship of the *Monarch's* commander, Capt. J. P. F. Betson, and his officers and crew.

A second, and worse storm was encountered upon the return to Rockall. This was a manifestation of hurricane Ione, with wind velocities of over 100 mph and very high seas. The ship had given up searching for the buoy (later reported drifting more than 500 miles away off the Faeroe Islands) and was grappling for the cable, when the storm hit. Fortunately, the cable had not yet been found, so the ship could head into the wind and ride it out. She was driven many miles off course in the process, and the seas will be long and vividly remembered by all present. Incidentally, the cable was picked up shortly after the storm had moderated.

Generally speaking, the effect of the weather on the engineering supernumeraries on board was not severe, although the *Monarch's* stock of dramamine was somewhat depleted by the end of the project.

Miscellaneous Events

At the start of the first transatlantic lay, several icebergs were encountered. A small one at the mouth of Random Sound lay in the path of the cable and therefore caused an involuntary, though minor, revision of the route. The others, beyond the mouth of Trinity Bay were larger, but also farther away. Whales and grampuses became common sights, though much photographic film was expended at first by the uninitiated. An occasional bird rested on the ship far from land, obviously exhausted from its long and presumably unintended journey.

Progress Bulletins

Daily progress bulletins were radioed to headquarters of all partners during the laying. In addition, because a telephone cable system differs considerably from submarine telegraph cables, the officers and crew were briefed by the engineering personnel as to the repeater structure, the need for equalization, and the general objectives of the venture. This proved to be a very profitable move indeed, for the co-operation of all hands was everything that could be wished. As a follow-up, daily performance bulletins were posted in strategic parts of the ship so that everyone, no matter what his duties, could know just how the evolving system was performing with respect to objectives.

Cable Order Circuit

One-way conversation from shore to ship over the cable was possible all the time the repeaters were energized. This was a source of very great satisfaction to the shipboard test crew, as it was concrete evidence that the cable was working, and working well. When power was turned down, the recourse to radio telephone provided a comparison which generally left no doubt as to the future value of the cable.

When the final splice was slipped into the water of Clarenville Harbor, on August 14, 1956, there was completed a venture quite unique in the annals of submarine cable laying. And in the laying perhaps more than in any other phase of the transatlantic project the successful conclusion provided evidence of the friendly and harmonious relationships among the different organizations and nationalities involved, and of the close co-ordination of their efforts.

LATE DISCUSSION

The following discussion was received too late to be included with the paper.

Discussion of paper 56-207 by Kan Chen and A. J. Schiewe, published in Communication and Electronics, Sept. 1956, pp. 396–400.

A Single-Transistor Magnetic-Coupled Oscillator

Kan Chen and A. J. Schiewe: The authors wish to thank Mr. Van Allen and Mr. Mortimer for their discussions of this paper. In particular, Mr. Mortimer is to be commended for his fine work which is recorded in his Naval Research Laboratory report. His efforts appear to be very nearly parallel to those of the authors in regard to the single-transistor oscillator.

The ideas presented in our paper are intended to give a complete explanation of the operation of Van Allen's circuitry. This, then, forms a basis for the logical development of the single-transistor oscillator. It is felt that past reports, although possibly dealing with essentially the same circuitry, have neglected such an approach.

Chronologically, our work, just as Mr. Mortimer's, was preceded by a much wider effort in solid-state device research which was being carried on by Westinghouse Electric Company. A review of records indicates that a Westinghouse materials engineering department engineering report, from which our paper evolved, was issued on February 24, 1955. The publication of our work in its present form was delayed by the fact that one of the authors is now at Purdue University.

ERRATUM

"Dynamax, a New Crystal and Domain-Oriented Magnetic Core Material" by G. H. Howe, published in Communication and Electronics, November 1956, pages 548–51, closure by G. H. Howe.

An error was made in reproducing Figs. 4 and 5. They should be transposed, so that the right-hand chart appears over the caption "Hysteresis loops of 2-mil 65 permalloy," and the left-hand chart appears over the caption "Hysteresis loops of 2-mil Dynamax."
